Dermatitis Due to the Irritating Effects of Metol.—N. T. Beers says that this remedy is a synthetic white powder, the use of which is practically limited to photography, in which art it is employed in developers as a reducing agent alone or with such agents as pyrographic acid or hydrochinone. In these days of amateur photography we are often called to treat conditions of the skin of the hands due to this agent. In a general way the substance is a direct irritant or vesicant, and presents no special appearances. Its effects are generally confined to the fingers and hands, and show no inclination to spread by contact or autoinoculation. The picture resembles a mild case of ivy poisoning. Certain prophylactic measures are suggested by the author for the benefit of photographers. The main indications for treatment are rest and protection. Several favorite prescriptions for the latter purpose are given by the author.

Neurasthenia Ventriculi and Gastroptosis.—According to H. Weinstein, the most constant and important symptoms of this condition are pain, pressure in the epigastrium, pyrosis, sour eructations, globus hystericus, nausea, vomiting, anorexia, abnormal appetite, a sensation of emptiness referred to the stomach, difficulty of deglutition, indefinite pain in the back, abdominal cramps, constipation, or diarrhea alternating with constipation, attacks of faintness and of impending dissolution, tachycardia, headache, and dizziness. In addition, there are various manifestations indicative of vasomotor affection. All these symptoms may be present in a given case, or only a few principal symptoms masked by a great number of bizarre and unusual sensations. In the endeavor to locate the tender area over the gastric region, a suddenly applied blow of the finger over the epigastrium will call forth resentment on the part of the patient as well as of the abdominal muscles, and pain will be complained of whether it is present or not. It should be performed in an easy and methodical manner by pressing the epigastrium with one finger very lightly at first, constantly and gradually increasing the pressure until pain is complained of. The importance of distinguishing between a mere hyperesthesia and pain due to organic disease cannot be overestimated as much from a positive as from a negative standpoint. The author adds that heartburn and sour eructations are apt to be present in those periods if a neurosis is overacid, but there are exceptions to this rule. In gastric prolapse there is often the sensation as of a foreign body in the throat. It is frequently aggravated after eating. It may be due to the dragging of the prolapsed organ on the esophagus. A sensation of emptiness in the stomach and of abnormal hunger is often present in overmotility, but it may also be due to a purely nervous condition. In prolapse of the stomach the colon is also displaced to a greater or lesser degree, and as a result there is constipation. Owing to decomposition of the fecal matter and formation of noxious substances, a colitis develops sooner or later with a resulting diarrhea.

Journal of the American Medical Association, September 12, 1908.

Renal or Vesical Calculi?—C. Beck reports two facts observed by him, which tend, he thinks, to modify somewhat our views as to the origin of calculi in the urinary tract. The first of his conclusions was reached by his finding in eleven cases of vesical calculus in the space of four years, that in nine of them the *x*-ray showed renal calculus coexisting. In the other two technical defects occurred, rendering the result doubtful. While the majority of authorities hold that most calculi originate in the kidney, some still hold

that a large percentage are of vesical origin. Prior to the use of the *x*-ray there was no proof to the contrary. Beck is satisfied that in the nascent calculus the solids that are normally dissolved in the urine are in some way precipitated, and he thinks that they are then much more liable to be arrested in the windings of the renal structure than in the regular surfaces of the normal bladder. They need not necessarily be in excess; some exciting cause, foreign substances, necrotic tissue, mucus, or blood clots may serve as a nucleus, and in this connection he refers to his observations on tuberculous kidneys in which the bacilli formed the starting point. Where no such conspicuous cause is known, however, the exciting cause of the precipitation is, as in the gall-bladder, unknown. In the overwhelming majority of cases it would be impossible to say, without the aid of the *x*-ray, whether the calculus is of renal or vesical origin, but Beck believes that, save in the unusual conditions or foreign substances, etc., mentioned above, the starting point is in the kidney, though the later development may be in the bladder. The cases of so-called ascending infection in vesical calculus are, he thinks, to be taken *cum grano salis,* as the pyelonephritis may be just as likely due to unrecognized renal concretions. If calculi are admitted to be of renal origin, the therapeutic importance of the fact is evident, after removing the calculus the nephrolithiasis is to be considered. Beck's second conclusion is based on his observation that in vesical tumors incrustations are sometimes so abundant that calculus is diagnosed. Even cystoscopy sometimes fails, moreover, when a calculus is encysted. The *x*-ray and the cystoscope are both essential for a certain diagnosis; neither is alone sufficient. He reports a case in which the *x*-ray alone led to an erroneous diagnosis of calculus due to calcareous incrustations of a carcinomatous tumor.

Non-Tuberculous Arthritis.—H. W. Marshall has studied the clinical material in the way of rheumatoid arthritis in the Massachusetts General Hospital, and in the private practice of Dr. Joel Goldthwait. Bacteriological specimens have been made of the stools of a dozen patients to determine the predominant type of organisms in the intestines, and blood cultures have been made from as many more cases, while agglutination tests have been tried a few times on bacteria isolated from the feces with negative results. The effect of fermented milk on intestinal putrefaction was experimented on in some private patients, but with rather inconclusive results. The advance made in the investigation, he thinks, can be best shown by a report of two cases representing types of the disease in acute exacerbation of the chronic trouble, for it was found that the slow processes of the very chronic cases were hard to identify. The first case was that of a woman aged 35, who had acute exacerbations since she was 2 years old, and was markedly relieved for a time by ether inhalation. Further experiments on six patients demonstrated that ether does influence the arthritic process temporarily, and this subject will be further investigated and reported on. Apparently, the ether circulating in the blood temporarily stimulates the protoplasm into normal activity and increases the nitrogen metabolism. In another type of cases ether aggravates the condition and these are probably infective. The second case reported was of this type and the patient was benefited by the use of fermented milk with daily enemata of normal salt solution which cleared the intestines of masses of hitherto unsuspected retained fecal scybala. Intestinal toxemia was here accountable for the conditions. Two other observations which strengthen the arguments for a metabolic type of arthritis are also mentioned. One was a woman whose symptoms cleared up during pregnancy and the other was a man who had a temporary relief during convalescence from lobar pneumonia.

Radium Salts for Cancer.—F. H. Williams gives his experience with the use of radium in the treatment of some superficial cancers and other cutaneous disorders. The chief therapeutic effects seem to be from the beta rays, fourteen times as much of which as of the gamma rays are given off, as shown by the fluorescence produced. Besides cancers, it seemed to be useful in acne, psoriasis, eczema, warts, and keloid, and gave rather encouraging results in two cases of trachoma. In 68 cases of epithelioma, with an average duration before treatment of four and one-half years, the lesions healed in 55 patients; 4 are under treatment; in 1 healing failed; and 8 stopped treatment, all, with one exception, doing well at the time. One case is reported. In his method, the capsule containing 50 mg. of pure radium bromide, on a handle a foot long or more, was applied over each area treated, for a period varying from one-half to three and sometimes four minutes, from one to three times a week (less often after healing has begun), according to the case. His conclusions are given as follows: "1. The radiations from radium are uniform in quality and quantity, and thus this remedy has a great advantage over the *x*-rays in efficiency and safety. 2. The gamma rays from radium are useful in some cases for relieving pain. They have great penetrating power. When they are used as an analgesic the beta rays should be excluded or the patient may be burned, partly because the proportion of gamma rays is so much smaller than that of the beta rays that the exposure must be much longer, when the gamma rays are used, to make them effective. 3. The beta rays from radium are the useful rays in the treatment of rodent ulcers, epitheliomas, and other superficial diseases. They can be applied in the mouth and other cavities. 4. Radium should be used early, and in suitable amount and strength. The treatment is painless and leaves least scar. 5. Radium does not produce as good results in cases in which an operation has first been done, or scraping, caustic, or other irritating treatment has been used, or the *x*-rays have been applied. 6. Improvement follows the use of radium more promptly in many cases than the use of the *x*-rays, and the total duration of treatment by radium, though sometimes long, is much shorter than with the *x*-rays. In some cases success has followed the use of radium when treatment by the *x*-rays has failed. 7. A surprisingly large proportion of external cancers, especially epitheliomas, having healed and remained healed for some years under treatment by radium, my experience thus far indicates that in certain cases of external new growths it is a better remedy than those previously at our command. 8. Recurrences follow all methods of treatment, and radium is no exception, but, so far as present experience goes, this is unusual, and they have yielded to further treatment by radium. 9. The disadvantage of radium is its cost to the physician."

Uterine Displacement.—H. J. Boldt says that with the advances in operative surgery, the practice of minor gynecology has almost been lost sight of. We should remember, however, that all patients are not alike suited for surgery and that no operation is entirely free from risk. He points out that a considerable number of acquired retroversions and retrodisplacements, not fixed by adhesions, are amenable to treatment by pessaries, which, however, should never be used until the uterus has been placed in physiological anteflexion. The cases best suited for this treatment are the recent postpuerperal ones, hence the importance of examination of these patients about a month after confinement. If the physician is specially trained in the Thure Brandt method and can give the time, and the patient is willing, much can be accomplished in cases with adhesions, especially old postpuerperal cases. There are also some backward displacements with light adhesions that can be broken up after the Schultze method under anesthesia at one sitting. In acquired pathological anteversions and anteflexions, pessaries are useless except for the relief of the vesical tension. Congenital anteflexions, usually with retroverted cervix, are due largely to shortening of the rectouterine ligaments and frequently associated with posterior perimetritis. Pessary treatment is useless in such cases, so far as Boldt's observations go.

Prognosis of Neoplasms.—G. McConnell questions the common opinion and the statement in textbooks that the number of actively dividing cells found by microscopic examination of malignant growths bears a definite relation to the rapidity of the progress of the disease. He has investigated a considerable number of tumors of various types, squamous epithelioma, carcinoma, and rodent ulcer, and found no such relation to exist sufficient to warrant conclusions from the previous history or later progress of the disease. He concludes that it is not wise for the pathologist to give a prognosis from his microscopic examination. It would seem advisable also not even to suggest that the tumor is taking on a rapid growth, as the clinician might thereby be deceived.

The Lancet, September 5, 1908.

A Localized Outbreak of Scarlatina Presumably Attributable to Milk.—C. A. Cameron refers to an outbreak of the disease in Dublin. In the course of six weeks 37 cases were reported. Of these 16 were reported within a period of 12 days, all living within a radius of less than three-quarters of a mile. Every one of the patients had been supplied with milk from the same dairy. Examination of the property of the

dairyman, employees, family, etc., failed to discover any recent cases of scarlet fever. One of the workmen had severe tonsillitis with fever. He was isolated and kept under observation, but no desquamation took place. Another workman had a slight sore throat. The cows were apparently free from any infection. Under these circumstances the health officer could not prevent the sale of milk from the dairy, but all the utensils of the latter were disinfected and as well the house in which the workmen lived. The author admits that his conclusion that the dairy was the source of infection is a rather lame one, for no case of the disease was found in connection with the dairy, and many of the customers of the latter were not infected; in fact, but a few of them. It does not follow, he says, that all the milk from the dairy was infected, nor were all those who consumed it in the particular receptive condition favorable to an outbreak of the disease. Yet he regards it as in the highest degree improbable that 16 cases of the fever should result from the use of this particular milk if it were free from pathogenic organisms.

An Outbreak of Cowpox.—An outbreak of cowpox in a dairy herd is reported by A. B. Green. During March of the present year the teats of several of the cows were chapped or cracked and two weeks later sores began to develop on the affected areas. Out of the herd of 27 cows 25 were affected. Soon sore places developed on the farmer's hands, on which papules formed with subcutaneous edema and reddened areolæ. Here some sores appeared later on the forehead and upper lip. In a few days the papules changed to vesicles which became umbilicated and exuded a clear fluid and in general followed the usual course of a severe and prolonged vaccination. Ten days after the first cases other cases developed in the laborers who assisted in the care of the herd. Examination of the exuded fluid revealed in the only pathological material, viz. the exudate from the hands of the farmer's son, the staphylococcus albus and aureus. Guinea pigs inoculated with this fluid developed typical vaccine vesicles. Two weeks later these animals were inoculated with highly potent calf vaccine and no specific reaction was noted. It seems evident, says the author, that the disease which affected the men's hands and the cows' udders was vaccinia. Endeavors were made to ascertain how the condition first appeared in the cows, but so far without success. No persons attending the cows had been vaccinated recently nor had any member of their families. The only other disease noticed among the farm animals was a few cases of foot-rot in sheep; and, from the experiments which the author has made, foot-rot material inoculated on guinea pigs, calves, and goats not only sets up no pathological conditions resembling vaccinia, but affords no protection against subsequent inoculations with calf vaccine. The farmer stated that his cows had on previous occasions suffered from sore teats, but according to his observations in not the same manner as on the present occasion. There is a possibility, therefore, that the vaccinia may have been endemic on the farm for some time. But the fact that no cow-men previously contracted vaccinia contradicted such a supposition.

Extensive Enterectomy for Gangrene.—The patient of A. E. J. Barker was a woman of 47 years, whose symptoms led to a diagnosis of appendicitis with perforation or possibly internal strangulation. The desperate condition rendered the employment of lumbar-puncture anesthesia advisable and 5 cgm. of stovaine and glucose were employed. The abdominal incision revealed a collection of dark, offensive fluid and a coil of mottled gangrenous bowel. On extension it measured 4 feet 9 inches. The healthy proximal and distal ends of the bowel were laid side by side and a lateral anastomosis made. The operation lasted seventy minutes and the patient felt no pain throughout. Recovery was uneventful, except for a slight disturbance from a stitch abscess. The history of the case showed that the gangrene occurred within 22 hours from the onset of symptoms. The section of bowel removed contained dark fetid blood under great tension, so that when the mass was felt through the abdominal wall it gave the sensation of a large cyst. The distal portion of the bowel for about a foot or so below the constriction presented a very interesting appearance such as the author has never before seen or known to be described. It was very irregularly constricted, portions being contracted and almost cord-like and portions dilated. Some unusual nerve phenomena must have been present, probably due to pressure by the band; otherwise it seemed to be perfectly normal in texture. No attempt was made to resect the bundle of intestine until the anastomosis had been effected. It simply lay outside the abdomen until the time came to cut it away and to suture the gap in the mesentery.

Exophthalmic Goiter; Pathology and Treatment.—Summaries of 16 cases are given by A. G. Gullan, who describes the cell changes which take place in the thyroid body and believes that its enlargement is a true hypertrophy from which results an increase of the specific secretion. To support this view he evidences the fact that the manifestations of exophthalmic goiter are the exact opposite to those of myxedema, which disease is undoubtedly due to a deficiency of thyroid secretion (athyroidism). The low ebb of metabolism in myxedema is clearly indicated by the infrequent low tension pulse, feeble cardiac action, mental and physical hebetude, subnormal temperature, dry swollen skin, constipation, diminution of the excretion of urea, and increase in body weight. Whereas excessive metabolism is shown in exophthalmic goiter by the frequent raised tension pulse, accentuated action of heart, mental and physical condition active and alert, temperature inclined to be raised, moist skin, looseness of the bowels, increased excretion of urea, and loss of body weight. There is no doubt that thyroid secretion is capable of causing intoxication. Assuming, then, that the hypothesis that exophthalmic goiter is due to intoxication from hypersecretion of the thyroid gland is correct, we have still no satisfactory explanation of the cause of the hyperactivity of the thyroid. It has been suggested that it is due to degenerative changes in the cervical sympathetic, or hyperplasia following an intestinal intoxication, but the intimate relation which exists between the thyroid and the generative organs—the gland often swells at the menstrual period, involutes or atrophies at the menopause, causing myxedema, hypertrophies at puberty or during pregnancy, causing exophthalmic goiter (this is illustrated in three cases of mine) inclines me strongly to the view that some abnormality in the function of the generative organs may be the starting point of the thyroid derangement. For medical treatment the author knows of nothing better than the antithyroid preparations. He advocates the use of rodagen in dram doses four times daily. It is expensive, however, and thyroidotoxin will doubtless give equally good results. Surgery appears to the author to be a logical and scientific method of treatment except that we cannot be certain that compensatory hypertrophy will not take place in the portion of the gland left behind.

Berliner klinische Wochenschrift, August 24 and 31, 1908.

The Specificity of Wassermann's Reaction in Syphilis.—Boas and Hauge deny the truth of the findings of Much and Eichelberg, who have claimed that the Wassermann reaction for syphilis can be obtained with the blood of scarlet fever patients. The authors have examined sixty-one cases of scarlatina in reference to this point; in one case the reaction occurred, but it was no longer present two weeks later. The reaction discovered by Wassermann is therefore specific for syphilis with very rare exceptions. The appearance of the phenomenon in the case of scarlet fever patients has not as yet been explained.

Pseudometastases in a Case of an Ovarian Dermoid.—Melchior reports a case of this condition and abstracts four others from the literature. His patient was operated upon for an ovarian cyst which proved to be a dermoid. The peritoneum was found to contain thick, porridge-like material which was escaping from a rupture in the wall of the cyst. Histologically the cyst was a typical dermoid, and contained hair, bone, and teeth. Three years later the patient returned with an inoperable carcinoma of the rectum. The autopsy disclosed the presence of a great many cysts with connective tissue walls attached to the peritoneum. The cysts were small in size, some possessed pedicles and the connective tissue of their capsules passed imperceptibly into the connective tissue of the peritoneum. The explanation of this picture the author finds in the rupture of the original cyst and the inflammatory reaction of the peritoneum with encapsulation of particles of the cyst's contents. Such encapsulated material on breaking off, may be the source of free foreign bodies in the abdominal cavity; the rupture of the original cyst may stimulate in severity of the symptoms the twisting of the pedicle of the cyst.

Acute Dilatation of the Stomach.—Borchardt says that the recognition of this condition is as important to the physician as to the surgeon. Its real significance depends upon the obstruction of the duodenum, with all the consequences which follow a high intestinal obstruction.

The oral portion of the duodenum and the stomach are dilated to an extreme degree, and are filled with bile-containing fluid which may collect in very large quantities, while the lower intestines are collapsed. The site of the obstruction is usually at the crossing of the duodenum by the superior mesenteric vessels; the cause may be found in the abnormal length of the mesentery, which allows the loops of intestine to descend very low into the pelvis and be fixed there, thus producing a pull upon the fixed portion of the duodenum. It is just as probable, on the other hand, that the dilatation of the stomach is the primary condition, due to some unknown change in that organ, and the obstruction follows this accident. The condition should always be kept in mind in cases of serious abdominal and general symptoms after narcosis, operations, errors of diet, and much vomiting. The symptoms begin with rising pulse, circumscribed swelling in upper abdomen, which soon reaches unusual degree, pain, vomiting, total constipation, and thoracic respiration. The temperature remains normal or only slightly elevated. The diminution of the meteorism following the introduction of a stomach tube differentiates the condition from peritonitis, but an acute disease of the pancreas is much harder to exclude. The prophylaxis consists in using the stomach tube in the very beginning of suspicious symptoms after an operation, etc.; the treatment consists of the same procedure, the stomach being thoroughly washed out. Ventral posture is favorable to the diminution of the obstruction, and should be always tried, except in the cases where the dilatation of the stomach has fully developed. Surgical treatment must be used if the simpler measures fail.

The Effect of Pancreatic Extract Upon Adrenalin Glycosuria.—Frugoni says that it has been proved that the injection of adrenalin can produce glycosuria, that such glycosuria may also be produced by painting the pancreas with adrenalin or by massaging the adrenals, and that the adrenalin glycosuria is accompanied by a hyperglykemia. His experiments show that such glycosuria may be prevented by a simultaneous or by a previous injection of an active extract of the pancreas. The latter substance is best injected intraperitoneally two hours before the adrenalin is used. In the test tube the pancreas extract changes the properties of adrenalin if kept in long contact with it, the toxic property leading to the appearance of diabetes being lost by the latter substance. The addition of certain salts prevents the loss of this property by the adrenalin, while the dialyzed pancreatic extract, on the other hand, is no longer able to modify the adrenalin in the above fashion.

Münchener medizinische Wochenschrift, August 25 and September 1, 1908.

Use of Fat-Free Tuberculin.—Jessen extracts the usual preparations of tuberculin with ether and then with chloroform, and mixes the resulting fluid with physiological salt solution containing 20 per cent. glycerin and 0.5 per cent. carbolic acid to make up any desired strength. This procedure removes the fats and waxes of the tuberculin which produce caseation and inflammation. The average dosage used is 1.100,000 c.c. and the injections are made at intervals of eight to four weeks. The site selected for the injections is usually the back where least local reaction occurs. Incipient cases are very favorably affected by tuberculin used in this fashion, advanced cases are sometimes likewise improved, but the progress of terminal cases cannot be stopped. No untoward effects have been noted.

Deformed Pelves.—Hegar says that deformed pelves are usually due to injurious influences that act after the birth of a child, though disturbances of development in intrauterine life may also be responsible for occasional cases. Among the most important of these influences is the loss of breast feeding, poor nutrition in early childhood, bad living quarters, too much schooling in unhygienic surroundings, early introduction to various diversions of social life, such as theaters, concerts, balls, etc., with the fatigue they occasion, and finally, chronic disease, such as rickets and tuberculosis. The effect of surroundings and mode of life is well shown by the large percentage of deformed pelves in Germany, contrasted with the comparative freedom from this condition among the active and athletic women of Sweden and Norway. It is the duty of the medical profession not only to assist the deliveries of women with deformed pelves, but to use every occasion to point out the means of preventing the deformity by protecting female children from the injurious influences enumerated.

Origin of Typhoid Epidemics.—Mayer tells his observations while on service in a sanitary station for fighting typhoid fever in South Germany. The disease may be spread by typhoid fever patients diagnosed as such, by light cases not recognized, by healthy persons harboring the bacilli, by convalescents or persons that continue to excrete bacilli a long time after the disease. Foodstuffs contaminated by the excretions of such persons, especially milk and green vegetables, have caused epidemics in several instances. August and September are the months in which most spread of typhoid fever takes place, while February, March and April show the lowest figures. High temperature is one cause of this phenomenon, hot, dry weather being especially favorable for the growth of the bacilli and the carrying of the infective material from place to place by the flies. Sanitary stations, therefore, should consider every case of diarrhea beginning in high summer as suspicious, while bacilli-carriers should be closely watched at these times and compelled to take the greatest care against spreading the disease. No remedies have been found that efficiently influence the excretion of bacteria by such persons; therefore, the hope at the present time lies in proper disposal of the sewage and excreta in the country as well as in the city.

The Dangers of Pessaries.—Cohn says that operative treatment of gynecological affections is properly taking the place of the use of pessaries, which often only led to neurasthenia in the unfortunate patient by reminding her constantly of her disease. The cardinal fault of the pessary is its character as a foreign body introduced in a cavity that responds to irritation by increase of secretion or by inflammatory reaction. The art of properly placing a pessary is very hard to learn and only a very good position of the pessary robs it of its dangerous or unpleasant effects. No material has been invented that does not irritate the mucosa of the vagina, does not get roughened on the surface or does not change its form in time. Often, too, the pessary is used by the general practitioner without clear indication for support, as in instances of infantile uterus, or as a placebo when no other treatment is available. Neugebauer's statistic has shown the frequency with which vesicovaginal and rectovaginal fistulæ are caused by this appliance; yet most of such cases are not reported in the literature. Ulceration is, of course, a more frequent consequence and when the increased secretion and the necessity of frequent douching is remembered the treatment by means of pessaries is plainly seen to be the least desirable form of dealing with gynecological affections except in a few well-selected cases. Still more harmful are the uterine pessaries which women use as anticonception remedies and which some physicians do not refuse to introduce. Such pessaries do not really prevent conception, but by irritation and inflammation they cause early abortion of the ovum. An abortion due to this cause is very frequently followed by endometritis and even general septic infection because the foreign body in the uterus favors the growth of pathogenic bacteria.

Deutsche medizinische Wochenschrift, August 27, 1908.

Fever in Tertiary Syphilis.—Dammert reports in detail a case of syphilitic infection in which various pulmonary and general symptoms occurred from time to time, always accompanied by intermittent fever. The diagnosis of tuberculosis, of malaria, of cancer of the liver were considered, but were disproved by the course of the disease. Finally, the administration of iodine and mercury was decided upon and the fever quickly and permanently disappeared. Dr. Pariser reports two additional cases in which specific therapy led to the disappearance of fever that had previously proved resistant to all other medication. All three patients showed remarkable improvement in general health, with increase in weight. The authors urge that the possibility of syphilitic fever should be remembered in all similar cases, with the history of a specific infection and some symptoms or signs, however slight, from the internal organs, especially the liver. The rise of temperature may be explained in such cases by the absorption of the products of breaking down gummata or the existence of a mixed infection.

Ova of Parasites in the Feces.—Telemann uses the following method of examining feces for the ova of parasites: Mix several small portions of the feces taken from different parts of the stool with a mixture of ether and hydrochloric acid in the proportion of 1:1. The ether dissolves the fats and fatty acids, the acid dissolves the soaps, mucus, phosphates, etc. Pass through a wide-meshed sieve to remove large undigested food remains. Centrifuge for one minute. The mixture separates into three layers, the upper consisting of the substances dissolved in the ether, the middle, of bacteria, small detritus, and the substances dissolved in the acid; the lower portion, often very small in quantity, contains food remains not dissolved in the ether or the acid, mixed with the ova of parasites. The ova are freed from fat and other material by the process and are easily recognized, even with low magnification.

Book Reviews.

Essentials of Surgery. An Outline of Surgical Pathology, Diagnosis and Treatment. For students and practitioners. By Alwyne T. Compton, F.R.C.S. Illustrated. Chicago: W. T. Keener & Co., 1908.

In this volume will be found the main points in connection with the etiology, pathology, diagnosis, and treatment of the chief injuries and surgical diseases. The general arrangement, headings, and classifications are unusually clear; there are several good diagrams, and the volume will readily enable the student to recall the chief points of such surgical affections as he has studied in a larger text-book, or seen in the wards.

A Text-book of Human Physiology. Including a Section on Physiologic Apparatus. By Albert P. Brubaker, A.M., M.D., Professor of Physiology and Hygiene in the Jefferson Medical College; Professor of Physiology in the Pennsylvania College of Dental Surgery; Lecturer on Physiology and Hygiene in the Drexel Institute of Art, Science, and Industry. Third edition, revised and enlarged, with colored plates and 383 illustrations. Philadelphia: P. Blakiston's Son & Co., 1908.

In this new edition of Brubaker's Physiology the whole text has been subjected to careful revision, and some new diagrams and new material have been incorporated. The new material, occupying some fifty pages in all, will be found in the chapters on the chemistry of the proteids, the physiology of muscle tissue, absorption, the physiology of the heart and vascular apparatus, the nervous system, and vision. There is a large number of busy practitioners who desire to have the important facts of physiology and an up to date presentation of the same, without the details of laboratory work and experiments. To such, the present volume can be recommended. The print, illustrations, size, and general get-up of the work are all that can be desired.

Leitfaden zur klinischen Untersuchung des Blutes. Von Dr. med. C. S. Engel in Berlin. Dritte Auflage. Mit 49 Textfiguren und 2 Tafeln in Buntdruck. Berlin: Verlag von August Hirschwald, 1908.

In the preface to this manual of clinical examination of the blood Paul Ehrlich, the creator of modern hematology, calls attention to the growing interest in the subject among practising physicians. The latter could select no better guide to the subject than the volume before us. It consists of seven chapters treating of the chemical and physical methods of examination of the blood, the morphology of the blood, its development and regeneration, the changes in its composition in disease, the blood parasites, and the biology of the bloodserum. Written by one of the most careful and original investigators in hematology, the book gives a complete résumé of our knowledge of the subject as well as an authoritative statement of some of the more important theories. The text is concise, readable and adequate throughout; there are many good illustrations in the text and the two colored plates at the end of the book give a very good picture of the general morphology of the blood in health and in disease.

Arterial Hypertonus, Sclerosis and Blood-Pressure. By William Russell, M.D., F.R.C.P. (Edin.); Physician to, and Lecturer on Clinical Medicine in, the Royal Infirmary, Edinburgh; Lecturer on Practice of Medicine, formerly Lecturer on Pathology, School of Medicine, Edinburgh. With thirty-six illustrations and plates. Philadelphia: J. B. Lippincott Company, 1908.

The purpose of this book, as stated by the author, is to direct attention to the important part taken by the blood vessels in the production of clinical phenomena, varying in intensity from trifling indisposition to severe illness. Dr. Williams first shows the lamentable faults in the nomenclature of the diseases of the blood vessels, such terms as atheroma, obliterative endarteritis and arteriosclerosis being loosely and differently used by the various authors. He limits the meaning of the latter term to thickening of the arteries not caused by atheromatous changes. Hypertonus, its causes, the clinical estimation of its degree by the sphygmomanometer are then considered. The rest of the book is given up to the study of various pathological conditions that have effect upon the blood pressure or are caused by changes in the pressure, among them, interstitial nephritis, disturbances of digestion, angina pectoris. The results of "hyopertonic contraction or spasm constriction" of cerebral vessels are considered last. The book is a monograph and does not pretend to cover the whole of the subject. It is, however, a very useful résumé of modern research and views of the nature of arterial diseases as well as of the original views of the author. It will prove very interesting to all students of arterial disease and its effect upon the organism, subjects which have recently been attracting much attention from the medical profession.

Sex of Offspring. A Modern Discovery of a Primeval Law. By Frank Kraft, M.D., Editor of "American Physician." Cleveland, Ohio: B. Barsuette.

The whole gist of this book is contained in the following quotation: "Accordingly, as fertilization of the ovum takes place at the period of flood tide or of ebb tide, so will male or female offspring accordingly result. It follows, then, that if we know the time of flood tide for any given locality, we may say for certain that the fertilization which takes place during that time will result in male sex—the nearer the middle of the rising water the fertilization takes place, the greater the certainty as to sex." So far as any argument is concerned, the author's thesis will hold just as well for the result of the next presidential election as for the sex of offspring. The volume has no scientific value whatever.

Ergebnisse der Inneren Medizin und Kinderheilkunde. Herausgegeben von F. Kraus, O. Minkowski, Fr. Müller, H. Sahli, A. Czerny, O. Heubner, Redigiert von Th. Brugsch, Berlin; L. Langstein, Berlin; Erich Meyer, München; A. Schittenhelm, Erlanger. Erster Band. Mit 28 Textabbildungen und 1 mehrfarbigen Tafel. Berlin: Verlag von Julius Springer, 1908.

This book is the first volume of a new periodical designed to appear once or twice a year and to contain original articles summarizing the progress made in the field of internal medicine and of pediatrics. The well known similar publications, one dealing with pathology and issued by Lubarsch and Ostertag, the other dealing with physiology, and issued by Ascher and Spiro, have won an enviable place for themselves among medical readers, and the book before us compares very favorably with these periodicals. The articles contained in the first volume are as follows: The relation between soul and body in questions of internal medicine, by F. Kraus; Adams-Stokes disease, by D. Pletnew; Digitalis therapy, by Dr. Fraenkel; Icterus, by Hans Eppinger; Experimental study of malignant tumors, by Carl Lewin; Pyloric stenosis of infants, by Ibrahim; Experimental arteriosclerosis, by Wolfgang Heubner; Arteriosclerosis of the central nervous system, by Cimbal; Salt metabolism and disturbances of nutrition in infants, by Meyer; Acetone bodies, by Magnus Levy; Allergy, by v. Pirquet; Researches in ferments, by Bergell; Biological study of infant feeding, by Salge; the digestion of milk in the stomach, by Tobler; Therapy of tabes dorsalis, by Frenkel-Heiden; Diagnosis of tuberculosis of the bronchial glands, by de la Camp; Pseudobulbar paralysis, by Peritz. The mere enumeration of the titles shows the great variety of subjects considered while the names of the authors belong for the most part to authorities or to active research workers in the special questions considered. To anyone actively interested in the progress of modern internal medicine the perusal of the volume before us will prove entertaining and profitable; to the research worker this volume and its successors will probably prove indispensable.

The Cause and Prevention of Beriberi. By W. Leonard Braddon, M.B., B.S., F.R.C.S.; State Surgeon, Negri Sembilan, Federated Malay States. London and New York: Rebman Company, 1907.

This work consists mainly of a report presented by the author to the Colonial Office of England, four years ago. A disease which attacks one hundred and twenty in every thousand of the Chinese immigrants, which is responsible for a death rate of 32 per 1,000, and which constitutes one-fifth of all the cases treated in the hospitals in the districts involved, is surely deserving of careful study. Such study the author presents in the volume before us. He begins with stating and criticising the various theories that have been held as to the causation of the disease, and then presents his own view *in extenso*. Briefly, he believes that beriberi is due to a poison found in rice, which is the result or the specific product of some organism—epiphyte or parasite—but he does not believe that the disease is due to the ingestion of the organism merely. The prevention of the disease is summed up in one page, and the gist of it is to secure a liberal and wholesome diet, and to avoid the use of rice or its extracts. "The only practical way to prevent beriberi in a community is for the State to prohibit the sale of any rice which is not either freshly made or which has not been cured by boiling or heating in the husk before stripping it." A complete bibliography is appended to the volume. The book contains a very thorough investigation of the etiology of the disease, and will be invaluable to all who practise where beriberi is prevalent. It has been gravely doubted whether the theory adopted by Dr. Braddon is the true one; but at any rate his book is honest, interesting, and timely.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Twentieth Annual Meeting, Held May 25 and 26, at Delaware Water Gap, Pa.

(Special Report to the MEDICAL RECORD.)

PRESIDENT, DR. CHARLES G. KERLEY, IN THE CHAIR.

Monday, May 5—First Day.

The Serum Treatment of Epidemic Cerebrospinal Meningitis.—Dr. SIMON FLEXNER read this paper by invitation. He expressed his appreciation of the flattering invitation that he had received to be present at this meeting, and said he would present some of the statistics that he had lately collected in regard to the treatment of cerebrospinal meningitis by the antimeningococcus serum. This serum had been used for just one year in this country and to a somewhat less extent in Great Britain, therefore what he said was based on less than 400 cases of epidemic cerebrospinal meningitis. The cases in which the serum was used had been diagnosed both bacteriologically and clinically. The manner of application of the serum had been somewhat modified during the course of the year, as they had learned more about the serum; they now gave larger doses and repeated the injections more frequently, The statistics of the last six months showed a larger percentage of recoveries than did those of the first part of the year. The favorable results of the last six months might be attributed partly to the fact that the existence of a serum for cerebrospinal meningitis was more generally known, and consequently employed earlier in the course of the disease. Some physicians said that they now saw the cases earlier than formerly, and this was a point of importance in deciding upon the value of the serum. It was of some importance to consider whether or not the serum was useful early or later in the same or different degrees. The serum belonged to the class of bacteriolytic sera; its capacity to neutralize was small. The pure antitoxic value of the serum was possibly not great. There was evidence on hand to show that the serum exerted a distinctly injurious effect upon the vitality and viability of the meningococcic germs present in the cerebrospinal canal. It was impossible to grow the microorganisms after injecting the serum directly into the cerebrospinal canal. There was a loss in the microorganisms soon after the injection was given. The chief advantage derived from the injection seemed to be from the injury to the microorganisms. Dr. Flexner stated that the figures that he had to offer were based upon 322 cases of cerebrospinal meningitis treated with the serum here and abroad. Of this number 247 were treated in this country. Of these 68 died and 147 recovered, a mortality of 27 per cent. He wished to emphasize the fact that these cases had not been seleced; some were late and desperate and some were mild. Those cases that came under treatment during the third week were the unfavorable ones and the case mortality would be higher than those that came under treatment during the first week. Sometimes only one or two injections would produce striking results in the patient; sometimes the results were most sriking in the desperate cases. In some of the cases the lumbar puncture, with serum injections, entirely changed the character of the disease and the patient went on to rapid recovery. Of these 247 cases, 13 were under one year of age and of these five died and eight recovered, a mortality of 37.5 per cent. There were 26 cases between one and two years of age; these also had a mortality of 37.5 per cent. There were 45 cases between the ages of two and five years; these had a mortality of 22 per cent. Between the ages of five and ten the mortality was 11 per cent. There were 57 patients between the ages of 10 and 20 years with a mortality of 28 per cent. There were 44 patients over 20 years of age, and these gave a mortality of 45 per cent. The average case got well gradually, the recovery extending over a period of days and weeks; he had been struck in noting the effects of the serum treatment with the remarkable abruptness with which a certain number of these cases terminated. This was what he meant when he said the disease terminated by crisis. Dr. Flexner said he thought the use of the word abrupt was better. Seventy-five of the cases were collected from Great Britain, where the mortality was about 30 per cent. Without the use of serum the previous mortality had been from 75 to 80 per cent. Dr. Flexner said he had assumed a mortality of about 33 per cent. The 322 cases gave a mortality of 29 per cent. The histories of the cases sent him showed that the periods of the active disease varied with the first injection of the serum, but he was struck by the fact that the period was of brief duration. The usual duration was two weeks. It was astonishing to see cases terminate in from two to five days. Charts were presented showing termination by crisis and by lysis. He thought that in a disease of such serious nature as cerebrospinal meningitis no therapeutic agent should be adopted as being of great value too soon. It should first be subjected to the most rigorous tests and judgment should be withheld until definite conclusions were reached. The persons to decide this question were those who saw patients before and after injection. The serum influenced the clinical course of the disease markedly, but he was unable to say just how it acted.

The Diagnostic Value of the Chemical and Bacteriological Examination of Cerebrospinal Fluid.—Dr. ALFRED HAND of Philadelphia said that lumbar puncture furnished a means of making an exact diagnosis. It was necessary, however, to examine the fluid with great care in order to arrive at a correct interpretation. Typical cases showed well-marked findings. If the fluid showed a milky opalescence which disappeared as the fibrin network formed and left a clear fluid containing a great increase in the normal amount of albumin, with the sugar but little, if any, below the normal percentage, the fibrin network also containing mononuclear leucocytes and tubercle bacilli, the diagnosis was clearly a tuberculous meningitis. When the fluid was distinctly turbid with sometimes a light yellow tint, polymorphonuclear leucocytes being found in abundance, some of them containing diplococci in their protoplasm, the diagnosis of epidemic cerebrospinal meningitis was established. After the fibrin network had formed and been withdrawn further study of the fluid showed a moderately increased amount of albumin and a total absence of sugar. In meningococcic meningitis the fluid was very similar with occasionally a greenish-yellow tint, as in streptococcic or staphylococcic meningitis, but the diplococcus was hardier; the pus cells were very abundant in the fluid. It was important to begin the examination as soon as possible after the fluid had been obtained. The fact that a tuberculous form was associated with the presence of sugar and an almost total absence of polymorphonuclear leucocytes while the reverse held for other affections caused him to think there was some relation between the two.

Hydrocephalus of Meningococcic Origin, with Remarks on the Serum Treatment.—Dr. J. H. MASON KNOX, Jr., and Dr. FRANK J. SLADEN, of Baltimore, presented this paper. A comparatively small number of cases of this kind had been reported in literature. With the onset of hydrocephalus the character of the symptoms seemed to change and the clinical picture in many cases was not recognized. Joslin, in reviewing the subject, mentioned a case reported in 1805 in which cerebrospinal meningitis was found in a person with marked dilatation of the ventricles. There had been numerous cases of hydrocephalus following meningitis reported. Some of these cases were reviewed. In many of the cases reported mental impairmnt was noted. They called attention to two cases treated during the winter and fall.

Case I.—This was a child of five months who had been perfectly normal at birth and for two months afterwards, when a marked gastroenteritis was developed which lasted seven weeks before the doctor saw her. At this time she was seized with general convulsions, followed by vomiting and fever. After two weeks these symptoms abated, retraction of the head was noticed, and the typical pressure symptoms of meningitis were found to be present. There was the bulging fontanelle with the bones of the skull separated and sutures gaping. The circumference measured 44 cm. One hundred c.c. of a slightly turbid fluid was removed in which a rather small number of organisms were found. There were numerous pus cells present. The child did well for a few days, but at the end of a week a second puncture was done and a similar amount of fluid removed. The family refused to have the serum used. The child improved for about a month, but a few weeks after died quite suddenly. Autopsy was refused.

Case II.—This patient was a child six months of age, who had been taken to a milk dispensary in Baltimore, where it was noticed that the child was markedly emaciated, with retracted head; the head was evidently hydrocephalic with bulging fontanelles. There was no history to account for the condition. The child was said to have had a fall. The left side of the head bulged more than the right. The case did not seem to be one of typical hydrocephalus and a tumor with pressure symptoms was suspected. A lumbar puncture with a dry cut was done. A ventricular puncture was then done and 20 c.c. of slightly turbid fluid was removed. A large number of meningococci, both extracellular and intracellular, were found by the pathologist. He learned that four months previously the child would awaken at night and moan as though in great pain. It had frequent convulsions and cried constantly. The eyes were crossed. The head had begun to increase in size about five weeks before admission and measured 46.5 cm. in circumference. The head was retracted and the neck held stiff. A second lumbar puncture yielded no fluid. Five intraventricular punctures were made which the child stood very well. He ran a temperature of from 97° to 101°, respiration from 24 to 40, and pulse from 100 to 150. The child finally collapsed and died. There was a lessening of the number of cases of hydrocephalus as a result of the use of serum treatment.

Case III.—This was a boy of fifteen years, who had been ill for ten days before having been seen. He was found in the typical posture of meningitis, was delirious and unconscious. There were six punctures made and a turbid fluid obtained. There was an improvement when treatment was instituted. Marked strabismus existed and otitis media developed and paracentesis was done on both membranes.

Case IV.—This child was seven years of age, and was seen rather early in the disease. He received two doses of serum. The patient began to convalesce and was discharged on the thirty-fifth day of the disease. There were 33 cases before this year, of which 21 died and 12 recovered, giving a mortality of 64 per cent. The lowest mortality occurred in 1899, when it was only 23 per cent. In 1899 they began to use lumbar puncture. During the last four and one-half months 21 cases had been admitted which were treated by lumbar puncture and intraspinal injections. Three died and 18 recovered. This was a mortality of 14 per cent. The three cases that died were of very virulent type. Twelve cases were under 12 years of age, 11 died and one recovered. Of ten cases seen previous to this year and under 12 years of age, four died and six recovered. Most of the cases were temporarily upset by the injection of the serum.

The Serum Treatment of Cerebrospinal Meningitis, with a Report of Cases.—Dr. Charles Hunter Dunn of Boston reported a series of 40 cases, occurring consecutively, treated by the serum. He included all cases in which the diplococcus was found without regard to type. Sixteen occurred in the Children's Hospital, 16 in private practice and 8 occurred in other hospitals. The serum was injected into the cerebrospinal canal in all cases. If the cerebrospinal fluid was cloudy the serum was used at once. Lumbar puncture was performed as soon as a suspected case was reported. In cases in which a rapid and marked improvement occurred after a first injection no further injections were given. In relapsing cases further treatment was given. The injections were repeated until the nervous and subjective symptoms were completely relieved, or until four injections had been given. The routine amount was 32 c.c.; the maximum amount was 45 c.c. Of the 40 patients, 9 died and 31 recovered. Thirty-nine of the cases were now entirely well. Clinically the type of these cases was not milder than those occurring before the serum was used. All types were included in this series. There were three fulminating in type with one death; six were severe, with two deaths; 19 were of ordinary type with one death. There were six mild cases with no mortality, and six late cases, in the chronic stage, unconscious when seen, five of which died. Up to 1903 lumbar puncture was the routine treatment. In 1906 the daily administration of diphtheria antitoxin was tried. In 1907 all cases were treated with vaccine prepared from the diplococcus. On November 1 the serum was used and there has been a drop in the mortality of 19 per cent.

The Serum Treatment of Epidemic Cerebrospinal Meningitis.—Dr. F. S. Churchill of Chicago reported the history of 11 cases, 9 of which were meningococcic in type. Four of the 11 cases died. One of these was a girl of sixteen years, who was brought to the hospital on the tenth day of the disease and was practically moribund. Another was that of a man twenty-five years of age who was brought in on the fifth day of the disease and upon whom the serum had no effect whatever. He said that he would devote his time to relating and illustrating the cases that had recovered. He had made observation on the effects of the serum treatment as regarded the temperature, the leucocyte curve, the spinal fluid as to leucocytes, bacteria, etc.

Case I.—This patient was a boy, sixteen years of age, who was seen on the sixth day of the disease. The first puncture was made on this day without any effect upon the temperature. The following day the serum was again injected and a decided drop in temperature followed, together with a cessation of the symptoms by lysis. Twenty c.c. was the dose given. The leucocytes persisted and the count which was at first 15,000 ran as high as 20,000.

Case II.—A boy sixteen years of age, who was seen on the second day of the disease, with a temperature of 102°. When the puncture was done it was 106.5°. A drop in the temperature followed the puncture, but it rose again later. Then three doses of serum were given sucessively. The temperature then dropped and did not again rise. The leucocyte curve had a varied course.

Case III.—A girl of nine years, who had a very severe attack. A puncture was done on the first day of the disease, with a marked drop in the temperature. The serum was injected on the second and fourth days in 30 c.c. doses. This case terminated in what Dr. Flexner called a crisis.

Case IV.—A boy, nine years of age, who was admitted to the Presbyterian Hospital on the twenty-first day of the disease. The serum was given every other day in 15 c.c. doses. On the twenty-ninth day there was a jump in the temperature, the leucocyte count, and a corresponding increase in the leucocytes in the cerebrospinal fluid. The clinical picture of the child showed a general increase. Three successive doses of the serum were given and the temperature returned to normal. Although this was a chronic and very persistent case, the patient made a complete recovery.

Case V.—A woman, treated at the County Hospital, upon whom lumbar puncture was done on the twenty-first day of the disease. The temperature dropped, but soon arose again. After being in the hospital for five days, with the temperature constantly up, 30 c.c. of the serum was given, and this was accompanied by a drop in temperature without a subsequent rise. After using the serum there was also a drop in the leucocytic count.

Case VI.—This patient was a Greek, nineteen years of age; and entered the hospital on the first day and the serum was injected on the second and fourth days, respectively, 30 c.c. of the serum being used. There was a fall in temperature after the injection, but a rise on the following day. The leucocytic count gradually fell to the normal. A lordosis made the spinal puncture a difficult procedure.

Case VII.—This was a child of ten years, having a very severe attack. The child appeared to be very ill. For three days successive doses of the serum were given, with good results on the temperature. The patient continued to run a leucocytosis 29,000, 16,000, then up to 25,000. A careful examination failed to account for this leucocytosis. Dr. Churchill said there was a general improvement following the administration of the serum. This improvement followed after the second or third dose. The mental condition showed marked improvement. It was interesting to see children with marked retraction of the head still much interested in their surroundings. There had been a decided drop in the number of leucocytes in the fluid at the time of the second, third, or fourth injection. There was a corresponding drop in the number of diplococci. This had been constantly noted. All the patients excepting two recovered without sequelæ. One patient had a mild nephritis when he came in, but he left the hospital apparently well. Another case ran a leucocytosis for which they could not account. Dr. Churchill believed that it was obligatory to do a lumbar puncture if one had a case of meningitis. The serum should be injected at once, and the form of meningitis that one was dealing with could be determined later. It was important to increase the dose day by day until one obtained good results.

Other Methods of Treatment Compared to the Serum Treatment of Cerebrospinal Meningitis.—Dr. Henry Koplik of New York said that it was apparent in the consideration of the various methods of therapy that they had lost sight of the natural course of the affection in the presence of some accidental unfavorable result, and in no case was this more common than in this affection. The disease resembled pneumonia very closely in its behavior. He thought all would admit that in sporadic cases of the disease one rarely met with the severe symptoms of the disease. In the sporadic form lumbar puncture only exceptionally revealed a purulent fluid at the onset. Cerebrospinal meningitis of meningococcic type very much resembled pneumonia in adults, and in sporadic and epidemic forms. In taking up the sporadic form he said he had the records of cases treated since 1899, and up to the epidemic years of 1904 and 1905. They had first begun the treatment of cerebrospinal meningitis in 1899 by lumbar punctures as often as the symptoms seemed to warrant the procedure. In the sporadic cases they had succeeded in saving life by the simple lumbar puncture. During 1899 and 1900 they had eight cases of meningococcic type. During 1901 and 1902 and 1903 they had 13 cases, thus giving 21 sporadic cases. Two of the infants below one year of age died. In the epidemic of 1904 and 1905 the history of the epidemic was a more violent one. Some died a few hours after admission. During the epidemic of 1904 there were 39 cases. Considering the patients below two years of age the total mortality was 50 per cent. He reported 13 cases of cerebrospinal meningitis treated by the serum therapy. No patients were punctured unless there were distinct indications for the puncture. Before a puncture was made the patient must have shown indications of an excess of cerebrospinal fluid. The serum was introduced by a funnel. The ages of the 13 children varied from three and one-half months to five and one-half years. Three were under one year of age; three were two years old or younger. The youngest child had been ill two weeks before admission, and was unconscious on admission. From 100 to 125 c.c. of serum was administered.

Dr. L. Emmett Holt of New York said that during the epidemic of 1904 statistics were collected of 2,350 cases, of which the mortality was 75 per cent. All were nonserum treated. As to the duration of the cases that recovered it was known that of 350 cases the disease lasted five weeks or longer in 50 per cent. This was a striking comparison with the reports at present. During the epidemic years they had treated 83 cases, and lost every one under one year of age. There had been so few cases during the past year in New York that he had seen few. One child of five months got well under the serum treatment. It seemed to him that the results of this treatment were very encouraging at present.

Dr. Thomas Morgan Rotch of Boston said that he had had good opportunities of watching these cases, and that he doubted the wisdom of speaking of epidemic and sporadic cases; the organism ruled the disease. Cases did not differ in any essential way, though they did differ in type. They had tried all courses of treatment in their wards, and had come to the conclusion that it was absolutely safe to give injections. This was important, as the disease was too serious to admit of delays. We already knew what happened when we waited. Lumbar puncture certainly did good temporarily, as it relieved the pressure. It also lessened the number of invaders, though this did not mean that there were not still a large number remaining to do damaging work. It had been found that vaccines helped in raising the opsonic index, though that might not be of much importance in our present knowledge of this subject. Vaccines might be of some help, but not so much as the serum. There was no doubt but that one should repeat the dose. We might at times save life by injecting twice in twenty-four hours. Immediate relief was sometimes given in cases in which the child was practically dying, but there seemed to be some prejudice against repeating the injection, and the symptoms soon returned. We might by pushing the treatment avoid some of the sequelæ. He was not afraid to give the serum, and to give it often enough. The youngest case he had seen was twenty-four hours old, and died the second day.

Dr. Frank J. Sladen of Baltimore said that in twenty-one cases in Dr. Barker's clinic the effect had been about as had been described by Dr. Churchill and Dr. Dunn. There was a rapid drop in temperature within twenty-four hours. In the majority of cases the temperature rose again, and required three or four injections before it remained at the normal. After the first drop the temperature did not rise again in three fatal cases. They found Kernig's sign most persistent. In regard to the effect upon the blood there was first a positive increase in polymorphonuclear leucocytes after the first injection. This had also been observed in other forms of meningitis. The typical fluid changed to a turbid one, with polymorphonuclear increase in six cases of tuberculous meningitis. This had also been noted in cases of influenza meningitis. So far as he had observed, there was no effect produced by the serum injections in pneumococcic meningitis. The extracellular organisms found in the first specimens were intracellular in the subsequent ones. The bacteria were destroyed, lost their staining power, and in some instances there was no growth after the first injection; in other cases the number of colonies was diminished. The rapidity with which the symptoms disappeared justified the idea of an antitoxic property in the serum.

Dr. A. Jacobi of New York said that he had no experi-

ence with the serum treatment of cerebrospinal meningitis. He raised the question as to whether anything could be done for those cases in which there was a subnormal temperature and which were generally fatal. In other septic diseases a subnormal temperature was usually associated with a complication. We expected a patient with diphtheria having a subnormal temperature to die. The question arose as to whether this subnormal temperature was due to a complication that we did not understand and as to whether there could be a treatment beside the serum treatment which would control this complication. Some bad cases of diphtheria which were not affected by antitoxin were helped by alcohol. While intoxication could not be accomplished, it should be attempted. Perhaps these cases of meningitis needed stimulation.

Dr. John Lovett Morse of Boston said that while his experience with the serum had not been as extensive as some of the others, he had seen a good deal of meningitis in past years. His experience had been mostly with babies. When we saw the organisms inside and outside the cells and obtained a culture and then the following day after an injection found no organisms outside the cells and a diminished number in the cells, and the next day no organisms and no culture, we could not doubt the efficiency of this method of treatment. He thought it was our duty to perform lumbar puncture on the suspicion that a case was one of cerebrospinal meningitis. The presence of the meningococcus was an indication for the use of the serum. If one found the fluid turbid, serum should be injected, without waiting to find the germs. He questioned the advisability of putting in the same amount of fluid that we took out. If there were meningococci in the fluid, the serum was needed. He had had a case where the first tap gave a very thick fluid, which showed meningococci. That baby needed serum. Two successive days following there was a dry tap, but the child still needed serum. He agreed with Dr. Churchill that a turbid fluid was an indication for the use of serum. He thought the serum should be used early and often; sometimes oftener than once a day.

Dr. Roland G. Freeman of New York said that he wished to emphasize the point that the serum might be of great value even very late in the disease. In Dr. Churchill's cases there were three in which the serum was followed by prompt reaction in a very late stage of the disease.

Dr. W. W. Wilkinson of Washington said that in ten cases at the Garfield Hospital in Washington they had seven recoveries and three deaths. One of the fatal cases had chronic hydrocephalus on admission to the hospital; another was in a comatose condition when he arrived, and though he improved after the injection of the serum, intestinal paralysis set in and nothing could be done for him. The third case he thought should not have proved fatal. Only one injection of 15 c.c. was given. The child improved, but the dose was not repeated and the organisms reappeared and the child died. They had had the best results with one injection of 15 c.c. or two of 30 c.c. on successive days. Four of the cases recovered with one injection of 15 c.c. The earliest day on which they had gotten a case was the fourth. The cases lasted about fourteen days after the first injection, but the bad symptoms subsided after four or five days. They found the organisms rapidly disappearing from the fluid and those in the leucocytes diminishing. They had also found an increase in the phagocytes, which was very marked in some instances. One of the fatal cases had a mixed infection. Of the cases that recovered in three there were sequelæ; one lost the right eye; one was deaf, and one had impaired mentality.

Dr. Samuel Adams of Washington said that he wished to make it emphatic that while clinical observation might not be of much consequence the results of clinical observation were of great importance. In many instances the sequelæ of this disease were worse than death. It would often be better if the patient had died rather than to have been left a burden on the community. From the results presented it seemed that we might avoid some of these sequelæ which occurred under other methods of treatment. His experience with the serum had been limited. He had had one child of seven months with pressure so great that it burst through the fontanelle. One injection of the serum caused a marked improvement in twenty-four hours. In a boy thirteen years of age, with most intense symptoms, convulsions and opisthotonos, a recovery followed the serum treatment. The stiffness in the neck persisted for two weeks, but the boy was perfectly conscious and intelligent. There had been proof enough presented to encourage further use of this treatment, which offered better results than any other method of treatment that had been tried for three decades.

Dr. Charles G. Kerley of New York said that this had been, in all probability, the most interesting session in the history of the society. They had considered a method for the alleviation and cure of a disease that had been considered hopeless, as far as medical means were concerned. He hoped that good reports would continue, and that they would not wake up to find that the hopes held out were more or less of a dream.

Dr. J. H. Mason Knox, Jr., of Baltimore said, in closing the discussion, that the clinical value of the serum had attracted more patients to the hospital than formerly came. He thought this should be emphasized. The statistics of Baltimore showed that there were more cases than usual, though there had been no epidemic.

Dr. Charles Hunter Dunn of Boston said, in closing the discussion, that he was interested in what had been said in regard to the injections causing pain. He had had two patients who had complained of pain in the back of the legs and knees. He had failed to warm the serum in these instances, and did not know whether that had anything to do with the pain or not. He did not mean to say that all cases with subnormal temperature died. He had had one that recovered after seven weeks' illness. All cases that passed over the period of active fever and symptoms and then went into a state of unconsciousness, with subnormal temperature, were very unfavorable. He had not been able to note any difference in the type of the disease in the so-called epidemic years.

Dr. Henry Koplik said, in closing the discussion, that he believed that we should not puncture except on indication. The object was not to relieve pressure only, but also to affect the organism. If one introduced 30 c.c. after withdrawing that amount of fluid, the following day the indication of the amount of fluid in the ventricle was less than the preceding day. If the child was doing well, he thought it superfluous therapy to puncture immediately again.

Dr. Simon Flexner, in closing the discussion, agreed with Dr. Koplik that meningitis was a very variable disease not only in different seasons, but in different localities. It had been very difficult to get comparative statistics. He had obtained the best statistics from Belfast, which was fortunate, because there had been an epidemic there during the past year. A mortality of 75 per cent. was reported during the height of this epidemic. Dr. Robb had secured a record of cases treated outside of hospitals, and these showed a mortality of 80 per cent., when it was only 25 per cent. during the same time in the hospitals. The cases outside the hospitals were probably not so well treated, and then they may have included a greater number of fulminating cases. Even this would not account for so great a discrepancy. There was an epidemic in Akron, Ohio, the year after the one in New York, where there were twenty-six cases, and more in the surrounding locality. Here there were two sets of statistics to be considered; one in which twelve cases were treated with serum, in which there were three deaths

and nine recoveries; a second series, in which there were nine cases, with eight deaths and one recovery. Dr. Flexner said that he stated these facts for what they were worth, and that he was not trying to make a strong case for the serum, though he did believe in it. The serum belonged to the class of bacteriological sera, in which we were obliged to use the antitoxic properties of the organisms. We now knew three antitoxic bacterial sera—diphtheria, tetanus, and dysentery. One could give an animal any amount of tetanus toxin, and if one gave the corresponding amount of antitoxin the animal would be saved. If one multiplied the toxin and antitoxin equally one got neutralization, but this was not true of the meningitis serum. The organism was grown and subjected to unfavorable conditions, and it underwent autolysis and yielded the extracellular toxin with which horses are immunized. It took many months to accustom them to considerable doses. The living organism was then used in order to secure a bacteriolytic property. When tested on animals it was found that it did not proceed according to the law of multiples, as did the antitoxins of diphtheria and dysentery. If one attempted to use a serum of this kind by subcutaneous injection, one must remember that a great deal depended upon concentration. When it was diluted too much with blood and lymph, it was not sufficiently strong to produce favorable results. He believed that success had been achieved because we brought a bacteriolytic, partially antitoxic substance in contact with the focus of the disease. He thought this was the secret of the matter. The fact to be emphasized was that this fluid must be in a certain state of concentration and brought into direct contact with the spinal membranes. The study of this question involved the question of the value of local applications. If a means could be found of treating pneumonia by some such method it should certainly be tried. It would not be sufficient to put it into the circulation; it should be brought to the focus of the disease. The reason we had failed with the sera might be because we had tried to reach local processes by putting the sera into the general circulation. It was right in diphtheria because there we had a poison that attached itself to the individual cells.

A Plan for Dealing with Atrophic Infants.—Dr. Henry Dwight Chapin of New York read this paper. He said that the usual form of dealing with the sick and ailing child of the poor consisted in attendance at dispensaries, day nurseries, visits of district physicians or nurses from the dispensaries and settlements, fresh-air excursions, etc., but there was one disheartening feature that occasionally confronted the work, and that was the wretched environment that they found surrounding them when they returned to their homes. The Speedwell Society was inaugurated in 1902. Children had been placed in carefully selected farms near Morristown, N. J. A doctor and trained nurse had constant oversight of the cases. The foster mother was instructed in the feeding and care of the children.

The supervisor nurse procured the children from the city and returned them to their homes. She also saw that the improved methods of caring for and feeding the infants were carried on after the child had been returned home. The total number of children cared for since the Speedwell Society was inaugurated was 817. Briefly summarizing a plan that had worked well and which was advised in the future dealing with neglected infants suffering from marasmus he offered the following: (1) Boarding out in a selected area of the country noted for its healthy conditions. (2) Constant attention to hygiene and diet on the part of the doctor and nurse who were familiar with that class of cases and competent to deal with them. (3) Infants were kept as long as necessary until feeding was regular and digestion and assimilation were improved sufficiently to result in an increase in weight. (4) To train up in a good neighborhood a number of foster mothers who, by taking these infants into their homes, became experts in handling them and were far superior to those offered by the best of institutions.

The Need of Post-Graduate Instruction in Pediatrics. Dr. Augustus Caillé of New York said that during twenty years as a teacher in pediatrics he had not met a single young hospital graduate, other than an externe of a children's hospital, who did not admit on inquiry his lack of knowledge regarding the line of professional work which made up one-half the practice of the family physician. Therefore it was evident that the present facilities for acquiring the knowledge necessary in this branch of medicine were wholly inadequate and that more practical instruction along the line indicated was urgently needed.

Modern Laboratory Feeding and the Wide Range of Resources Which It Provides.—Dr. Thomas Morgan Rotch of Boston said that what he wished to present was the result of his seventeen years' study which had been made in modern laboratory methods. He pointed out that the resources of the milk laboratories were such that physicians could prescribe combinations of any known food stuffs. The prescription of these compounds of food could be written for in percentages. Of special importance, next to the work of separated proteids, whey, and casein, was the possibility of prescribing the carbohydrates to a much wider extent than ever before. He explained why and how maltose was preferably used instead of lactose in cases where there was an overproduction of lactic acid, and how, on the contrary, where there was an overproduction of butyric acid, lactose was preferable to maltose. He showed how it was really not necessary to make use of the mechanical action of the starches in making the casein precipitate final, since the divided proteid accomplished this much better and much more intelligently. One of the greatest advances which had been made this last year in regard to the possibilities of laboratory modifications, when the physician wished to use laboratory methods, was the use of lactic acid or the lactic acid bacillus in pure culture. A strain of the lactic acid bacillus had now been obtained, which was seemingly successful in killing out the special ferment which produced the fermentative diarrheas. The physician could now prescribe a pure culture of the lactic acid bacillus in cases of this kind, and its use had been followed by the greatest success.

Dr. L. Emmett Holt said that he and Dr. Clarke were preparing a paper along this line which he regretted was not finished. One of their experiments was to determine the effect of lime water upon the gastric secretions. They used plain milk diluted with water, with lime water, and with soda solution, and found that the chief effect of the lime water was greatly to increase the secretion of hydrochloric acid. They had never found a deficiency of pepsin in an infant's stomach, but there was a great variation as to the amount of hydrochloric acid. They had removed the fluid from the infant's stomach after half an hour and put in the thermostat. After a short time digestion stopped and upon the addition of more hydrochloric acid it proceeded until the milk was entirely digested. This showed that the problem was to increase the quantity of hydrochloric acid.

Dr. Henry D. Chapin of New York said that he had recognized that proprietary foods sometimes did good, and he had written papers with the same object in view as Dr. Rotch had, namely, to find out if these foods could not be used scientifically by physicians. He believed the whole subject of infant feeding should be approached from the biological and not from the chemical standpoint. It was necessary to understand the digestive tract of different animals; milks were not interchangeable. The fact that milk had a developmental function as well as a nutritive function seemed to have been ignored.

Dr. Augustus Caillé of New York said the subject was a difficult one, because, when we put various ingredients in a test tube we could foretell the end results; but when we put them into the digestive tract we could not fore-

tell results, as we had to deal with secretions which varied and which were different when in motion from what they were at rest, and we also had bacteria to reckon with. All these factors made the problem very complicated.

Dr. J. P. Crozer Griffith of Philadelphia said that Dr. Caillé's remarks had encouraged him to say that he sometimes wondered it we were not all blind leaders of the blind. He wondered how this subject could be taught so that the student could comprehend and practise it successfully. He feared that elaborate laboratory schemes of feeding only discouraged the student, who would abandon them.

Dr. Wm. P. Northrup of New York said that to his mind pure milk was one of the greatest triumphs of the laboratory. The production of pure milk with an unvarying fat content was certainly an object lesson.

Dr. Rotch closed the discussion. He said that the way his paper had been discussed showed that there was a general interest in the subject. He thought Dr. Chapin was right in what he said, but he was not working in the same line. He was not working for students, but in order to find the best instruments to work with. He did not ignore the biological side of the subject, but that was not his line. He thought many men were using laboratory methods of feeding. Dr. Dunn could show case after case where lactic acid feeding had not been unavailing.

An Inquiry into the Status of the Kindergarten.—Dr. Isaac Abt of Chicago said he had written letters to physicians, mothers, and teachers asking their opinion of the kindergarten, and his paper consisted in a summary of the answers received. Of the physicians who replied 55.46 per cent. were in favor of the kindergarten and 21 per cent. were opposed to it, while 23.50 per cent. were indifferent. Of the mothers who replied 61.47 per cent. were in favor of the kindergarten and 22.87 per cent. were indifferent. The replies from superintendents and principals showed that 74.41 per cent. were in favor of the kindergarten, while 11.64 per cent. were opposed to it. Of the kindergartners themselves 96.15 per cent. approved. The chief objection to the kindergarten seemed to be from the physical standpoint; some thought that greater liability to contagious diseases and pulmonary affections existed.

Dr. Thomas Morgan Rotch of Boston thought that the profession might do much toward securing the proper management of the kindergarten in the future. Children should be classified according to their development and not according to age.

Dr. Wm. P. Northrup of New York said that while all were interested in infant mortality it was time we gave the older children a little more attention. We ought to take more interest in preserving the children while they were growing up.

Dr. F. S. Churchill of Chicago thought mothers and medical men had a wrong impression of the kindergarten. The well-regulated kindergarten only aimed to steer the mental development of the child. Unfortunately very few kindergarten teachers seemed to grasp this idea. These teachers should be well paid so as to attract women of high-class ability. The mother was not always the best trainer for the child. The professional was better than the amateur. Personally Dr. Churchill said that he believed in the kindergarten.

Dr. Henry D. Chapin of New York agreed with what had been said in regard to the need of teachers of a higher status. The entire public school system was wrong in this respect. The inexperienced teacher always got the lower grades and worked up. The early age was the critical time, the time at which the child should have the most careful training. This defect should be brought to the attention of legislators.

Dr. Charles G. Kerley of New York thought the whole matter depended upon the surroundings. If the child had proper surroundings and plenty of outdoor life the home was the best place for him, but to city children who lived in dirt and squalor the kindergarten was a godsend.

The Hard Curds of Infants' Stools; Their Origin, Nature, and Transformation.—Drs. Thomas S. Southworth and O. M. Schloss of New York presented this communication, which was read by Dr. Southworth. The discovery that firm, rounded curds, occurring not infrequently in the stools of infants fed upon cow's milk, were composed in part of fatty acids and soaps had led to considerable discussion and warranted a further inquiry into the origin of such bodies and their subsequent transformation during their passage through the digestive tract. Although certain theoretical and clinical grounds for considering such masses found in the stools to be identical in origin with those found in the vomited matter seemed reasonable and conclusive, a series of observations and tests were instituted at the Nursery and Child's Hospital to settle definitely some disputed claims. Foremost among these was the claim that the masses in the stools contained no proteid and only fatty acids and soaps. Typically firm curds occurring in seventy-five stools were passed by thirty-eight infants and subjected to qualitative and chemical tests to determine the presence of protein, soaps, fatty acids, and neutral fat. The hard curds were found to consist mainly of fatty acids and protein in varying amounts, although they uniformly showed the presence of neutral fat by stain reactions. Soluble soaps were found to be present, but apparently in smaller amounts than usually assumed. In every instance the final residue of the masses responded to all four of the tests for protein. The hardness depended upon the relative amount of protein, soaps, fatty acids, or neutral fat present.

Fat and Protein Content of Top Milk.—Dr. Charles A. Fife of Philadelphia read this paper. The Chapin dipper had been used in obtaining the top milk and the results epitomized were shown by charts. The fats in the top quarts showed the highest to be 32.2 per cent., while the lowest was 17.8 per cent. In milks of lower grades the variation was much less. In milks of higher grades the variation was much greater. The proteids were very uniform throughout, but in the higher grades the proportion of proteids was much less than was usually believed, about 2.75 per cent. As to variations between pints and quarts, the quarts were more uniform, as a rule, than the pints, and usually about one-half per cent. higher. With regard to the composition of the bottom milk there was very little difference between the lower twenty-four ounces and the lower eight ounces, so that it was not necessary to depend on the lower eight ounces to get a so-called fat-free milk. There was also very little difference as to the proportion of protein.

The Urinary Findings in a Series of Infants Suffering from Intestinal Infection.—Drs. J. H. Mason Knox and J. C. Meakins of Baltimore said that they had taken seventy-two infants as a basis for this study, of which nineteen were used as controls, in whom the urinary findings were negative and in whom there was no intestinal infection. There were six cases of malnutrition, six cases of diarrhea, four cases of indigestion, fifty-three cases of definite intestinal infection. No urinary changes were found in thirty-one of the fifty-three; in thirty-two definite abnormalities had been found. More than one-half of these fifty-three were in the middle of the first year. The duration of illness ranged from about ten days to six weeks. There were thirty-four boys and nineteen girls. They made three classes of cases according to the urinary findings: (1) Those containing only albumin, or albumin and casts. (2) Those containing pus. (3) Those in which in addition to pus there were albumin, casts, bacteria, and red blood cells. The conclusions reached by the authors of the paper were that infection in the urine occurred almost as frequently when the cases were toxic as when there was a very definite intestinal lesion, and that infection had its origin in the intestinal canal and reached the kidneys secondarily.

(*To be continued.*)

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Stated Meeting, Held April 21, 1908.

DR. ONSLOW ALLEN GORDON IN THE CHAIR.

A Medical Library and Its Contents.—Dr. JOHN W. FARLOW, Librarian of the Boston Medical Library, read this paper. He said that among the other valuable functions of the medical library was the collection and preservation of the portraits and biographies of distinguished medical men. The collection of monographs was an important function. The Sydenham Society was the first to attempt by means of monographs to bring valuable foreign medical literature within the ken of English readers. It was interesting to note that the *Journal of Mental and Nervous Diseases* was arranging for a series of English translations of foreign monographs. The student of medicine was to be impressed with the importance of a good reading knowledge of French and German. Medical education in America was now as good as could be obtained anywhere, and he who could read the foreign literature was certainly able to keep in touch with the latest expressions of medical opinion. The "abstracts" of foreign literature frequently gave an incomplete and distorted idea of the original article. The recent medical graduate gained most when he went abroad merely for the sake of learning the modern languages. It was important for the medical library to collect the proceedings of national and international congresses. Some of the best work of the day appeared in these. Every new special branch in medicine had its Centralblatt. This form of periodical literature was indispensable to the library. The question frequently came up as to whether it was a good thing for medical libraries to acquire all the new textbooks that appeared. The objection was made that these were frequently unduly bulky and soon became antiquated, while in many respects they were superficial. It was, however, well to recognize that what was superficial for one individual was indispensable for another. New books were to be welcomed; in fact, authors were to be encouraged in their endeavors. Periodicals were the backbone of the medical library. It was to be deplored that there were no dealers in second-hand medical periodicals in this country, for it was almost impossible to complete missing numbers in the files of the various journals. It was much easier to get second-hand foreign publications. The need of carefully compiled bibliographies was emphasized. The proofreading of the lists of references was not sufficiently attended to. It was desirable to use the system of abbreviations as adopted by the Surgeon-General's office at Washington. The Index Medicus was a monument to its founder, Dr. J. S. Billings. For twenty years it was of the greatest possible value, then during the four years of its discontinuance the record of current medical literature was practically buried. The Index Medicus was of inestimable value to the medical libraries. But the number of individual subscribers was not sufficient to repay the Carnegie Institution for its publication. The question was occasionally raised as to whether medical libraries should not become branches of general libraries. This question was best answered in the negative. It was better for doctors to manage their own literature. It was desirable that instead of having a number of scattered medical collections in one community, that all the books should be deposited in one central library. This was the case with the Boston Medical Library. It was becoming more and more necessary for medical libraries to acquire books pertaining to the numerous sciences lying in the borderland of medicine. The student of neurology and psychiatry was frequently searching for works on psychology. The advent of Christian Science and psychotherapy compelled the acquisition of books dealing with these subjects. Other subjects bordering on medicine were tropical diseases, comparative anatomy and veterinary medicine, in which subject students of scientific medicine frequently called for volumes. The close relation which medical science bore to other sciences imposed on the medical library the duty of opening its doors to the general public. Physicians did not realize that a great deal of reading matter came into their hands that might be of value to medical libraries; instead of consigning such material to the waste heap, it was better to send it to the medical library and let the librarian be the judge of its value. The speaker exhorted physicians who intended to donate books to medical libraries that it was better to give during their lifetime. The disposition of private libraries was usually omitted from wills, so that the auction room became the usual fate of the books. The speaker alluded to the good example of the Boston Orthopedic Club donating orthopedic pamphlets and a valuable set of *x*-ray plates to the Boston Medical Library. The medical libraries were growing away from the narrow confines of the past, and were reaching out for the newest and latest. But inasmuch as the present depended on the past, it was important that the library should treasure everything that related to medical men and events of former days.

Dr. JAMES P. WARBASSE of Brooklyn said that if there was any one thing upon which the people were to be congratulated it was living in a community where there was a great medical library. Unlike the country practitioner who did not have such library at his disposal, the city physician was no longer compelled to stock his own private shelves with books. The medical library was one of the strongest factors in cementing the bonds uniting the practitioners of a community. On this account the County of Kings had a much more united society than its sister across the river. The attitude of the profession in Brooklyn toward its library was most admirable. The Fisher collection that had recently been purchased was most valuable. The speaker alluded to the increasing use that was being made of the library, particularly by the young men in the profession. A critical time had come in the development of the library, a time when it was possible to appeal to the liberality of the wealthy philanthropist, with good reason, for the value of the medical library to the community at large was no longer a matter for debate.

Acute Intestinal Obstruction, with Especial Reference to Postoperative Obstruction.—Dr. JOHN B. DEAVER of Philadelphia read this paper. He said that this subject was of exceeding interest both to the internes and the abdominal surgeon; to the former, chiefly as a primary condition, and to the latter, mainly as a secondary complication. By obstruction was meant some occlusion of the intestine, but, in a broader sense, it occurred even when there was no mechanical occlusion, as in dynamic conditions. Thus, one could classify the condition into two groups, mechanical and dynamic. The first group included postoperative forms, strangulations, bands, torsions, gallstones, and foreign bodies. The second group included such forms as obstruction due to peritoneal adhesions, slits in the mesentery, and internal hernias, like hernia into the fossa duodenojejunalis. The symptoms varied in severity. The obstruction itself was not the important thing in the symptomatology. The important factor was the peritonitis. If this was present, it was sometimes too late for treatment. The pain of acute intestinal obstruction was sudden, usually referred to the umbilicus, and had no relation to the seat of the obstruction. The pain was due to traction. The textbooks stated that the pain was increased by pressure. It was questionable whether this was always the case. In rare cases the pain was inter-

mittent. Vomiting was an important symptom. Collapse occurred in the early stages. It was not a marked feature until the obstruction has been established for a few hours. In the postoperative forms the pulse was more rapid. As the obstruction continued, the patient's expression became anxious, he suffered great thirst, and the secretion of urine became diminished. It was important that the diagnosis should be made before the onset of collapse. Exaggerated peristalsis was frequently observed through the abdominal wall. When not seen, it could frequently be detected with the stethoscope. Occasionally the exaggerated peristalsis could be noted reaching a certain point, at which it would stop. It was more marked when lower down in the abdomen. It was usually easy to differentiate this condition from other abdominal conditions, such as acute appendicitis. With acute pancreatitis it was frequently confused. This difficulty was increased in acute cases when opium had been administered. The differential diagnosis, however, was of no importance as regarded treatment. Postoperative ileus was of greater importance than the primary variety; it was constantly occurring, and its presence had been revealed experimentally. There were three classes of cases: those occurring immediately after operation, those of ordinary mechanical intestinal obstruction, and those resulting from septic peritonitis. Those cases occurring immediately after operation, either on clean or septic cases, were dynamic forms and resulted from excessive handling of the viscera. Such cases also occurred after prolonged anesthesia. The rough introduction of gauze packs was also responsible for some of these cases. Not only asepsis, but also gentleness was necessary. Most instances of paresis of the gut occurred in septic cases, in which plastic exudation occurred. They were rare in clean cases. Insufficient drainage of pus or sero-pus favored paresis. The fact that drainage gauze irritated cut surfaces was the strongest argument in favor of tube drainage. The spread of peritonitis was sometimes unavoidable; the more the infection spread during the operation, the more liable was it to produce obstruction. Obstruction due to thrombosis or embolism of the mesenteric arteries was difficult to diagnose. The mechanical ileus was delayed, the pain was sharp, sudden, and localized, and vomiting did not necessarily occur. There was a great degree of anxiety and restlessness, meteorism developed, and the pulse was greatly elevated. Constipation was not absolute. In mechanical ileus due to adhesions the prognosis was good if the case was early recognized. During the past three years the author had seen seventeen cases of postoperative ileus, eight of which were the result of adhesions, and four of which were dynamic ileus. Fifteen of these cases were operated upon, with a mortality of 50 per cent. In a record of 4,000 operations one-fifth of 1 per cent. were postoperative obstruction. The speaker then discussed the treatment of this condition. When intestinal obstruction was primary, occurring in a previously healthy individual, the patient's only hope was an immediate operation. It was fatal to wait for fecal vomiting. The operation was not to be undertaken as a last resort, but as the first step in the treatment. It was to be deeply regretted that the use of morphine was responsible for delay. There were surgeons who recommended the use of morphine in postoperative ileus; a good nurse was better. The speaker said that if any of his house-surgeons gave morphine in this condition his resignation would be instantly demanded. In the preparation of the patient for operation, lavage was to be performed, but this was not to be done under anesthesia. The complete operation was advised, the relief of the obstruction was to be dexterously performed, and the distended bowel emptied. The treatment of postoperative obstruction began before the operation. If a case was allowed to go on to suppuration, intestinal obstruction was invited by delay. All unnecessary handling was to be avoided. In septic cases drainage, preferably with rubber or glass drains, was to be resorted to. The speaker did not use injections of eserine. In the presence of a great angular obstruction, enteroenterostomy was sometimes necessary. No solid food was to be given for two weeks after the operation, and for the first few days only water was to be given. One of the chief causes of postoperative obstruction was morphine. The good effect of eserine was manifested only by relieving distention, but not obstruction. As regards prognosis, the most important point was that delay reduced the chances of recovery.

Stated Meeting, Held May 19, 1908.

DR. ONSLOW ALLEN GORDON IN THE CHAIR.

Some Common Injuries of the Elbow Joint.—Dr. JAMES P. WARBASSE of Brooklyn read this paper. He said that fractures of the condyles had been unfortunately termed fractures of the elbow. In order that such fractures might be properly treated a thorough knowledge of the anatomy of the parts and of their centers of ossification was necessary. The condyles did not unite with the shaft until the fifteenth year. It was before this time that the greater proportion of condyloid fractures occurred. There were many misconceptions of the proper treatment of this condition. In a fracture of the internal or external condyle or separation of the epiphysis in a child under 15 years, good union of the parts usually took place, and this was as a rule considered by the surgeon a good result. But the intervening cartilage was frequently turned into bone, with the result that the growth of the corresponding side of the lower end of the humerus was arrested. Thus, in a child 10 years of age, the growth that would have continued for five years more was rendered impossible. In this manner fracture of the inner condyle resulted in obliteration of the carrying angle. Cubitus varus or the gunstock deformity was the acme of poor results. The common fear of ankylosis in fractures of the lower end of the humerus was unwarranted. This fear led frequently to irreparable damage from a too early attempt at passive motion. If the fragments were placed in good apposition in the young and if immobilization was maintained for three or four weeks, then a perfect result was to be expected. If the immobilization was perfect there was little callus. The speaker emphasized the value of treatment, by means of extreme flexion, of fractures of the lower end of the humerus. This was particularly applicable to fractures of the condyles. In certain cases it could not be applied. There were cases of condyloid fracture and epiphyseal separation in which the lower fragments were prevented from moving into position by the long unbroken ligaments. The first essential in the treatment of elbow injuries was a knowledge of elbow anatomy. It was desirable to compare the injured with the sound elbow. In the latter, with the forearm flexed, at a right angle, the tips of the internal and external condyles and the tip of the olecranon were in a straight line. With the forearm extended they formed the angles of an equilateral triangle. It was to be noted whether the carrying angle was the same on both sides or not. The existence of local points of tenderness and crepitus was also to be investigated. The *x*-ray was almost indispensable.

The Diagnosis of Certain Chronic Abdominal Conditions.—Dr. WALTER C. WOOD of Brooklyn read this paper. He said that the interest of surgery in the abdomen first concerned itself with the diagnosis and treatment of tumors. The interest in acute abdominal diseases did not come until later. As time advanced, the operations that were at first attempted by the leaders only were commonly performed by younger and less experienced men. The recent achievements in the surgery of abdominal conditions wre such that those in general practice should appreciate the necessity of making a diagnosis in time for proper surgical intervention. To a greater degree this

necessity was true of the surgeon. There was too great a tendency for the surgeon to rely upon the exploratory laparotomy, without making the necessary preliminary study of the case for the purpose of diagnosis. Without a thorough preliminary study and observation of the case even the findings at the exploratory operation were frequently confusing and unintelligible. Thus, there were a number of conditions associated with adhesions about the duodenum, enlargement of the head of the pancreas, and changes in the gall-bladder and its duct, in which from inspection alone it was impossible to determine which was the primary condition. The haste to operate was seen in the large number of cases subjected to operation in which the abdominal pain was that due to locomotor ataxia, Potts' disease, lead colic, etc. Of course, in acute cases prolonged preliminary study was not possible, but in chronic cases at least a few days of careful study was desirable before operation. It was the lack of this study that accounted for the loss of prestige on the part of surgery in some quarters. It was characteristic of specialists to magnify details. Sometimes they saw too much. The clinical history, the physical examination, and the laboratory investigation were the tripod upon which the diagnosis was to rest. Although the most important of the three, it was the clinical history that was too frequently neglected. Although the abdominal condition was a chronic one, it was frequently characterized by periods of quiescence, alternating with periods of exacerbation. For example, ulcers of the stomach healed and then broke out again in other places, like ulcers of the leg. Ulcers of the duodenum produced indefinite periodic attacks of pain, occurring three to five hours after eating. Similarly gallstones, whether or not impacted in the common duct, gave rise to symptoms occurring in attacks. Likewise, chronic inflammations of the appendix, tuberculosis of the peritoneum, kidney lesions, and diseases of the tubes gave rise to symptoms characterized by their periodicity. It was necessary to understand the significance of vomiting, which was either reflex or toxic. Vomiting, in combination with epigastric pain, usually indicated a stomach lesion. Certain lesions of the digestive tract remote from the stomach had vomiting as an important symptom. Pyloric spasm was not a distinct disease. It occurred in duodenal and intestinal ulcer, inflammation of the appendix, etc. Spontaneous epigastric pain occurred in various functional and organic abdominal diseases, but not all epigastric pain meant abdominal disease. The diagnostic importance of the relation of epigastric pain to the taking of food was commented upon. In ulcer of the stomach pain occurred one hour after eating, and was relieved by a glass of milk. In ulcer of the duodenum pain occurred three or four hours after eating. The pain in gallstone disease was irregular as to the time of its occurrence. The attacks of pain occurring in chronic constipation were to be borne in mind. The abdominal pain of neurasthenia mimicked that of a number of abdominal diseases. Gastroenterostomy was certainly not the ideal treatment for neurasthenia. Loss of weight was usually caused more by restrictions in diet than by the abdominal condition itself. It was less frequently caused by malignant disease. The production of gas was an early symptom of ulcer of the stomach or duodenum, and in chronic peritonitis the physical examination was less important than the history of the case. The chief symptom of local disease was always the local point of tenderness. The repeated laboratory examination of the feces for fat and meat was more trustworthy than the examination of the stomach contents. The search for occult blood in the stools was important. The finding of gallstones in the latter settled the question of the diagnosis of gallstone attacks.

Dr. Dudley Roberts of Brooklyn said that he agreed with the speaker, that the laboratory examination of the feces was more important than that of the stomach contents.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners, South Dakota.

Examination January 8 and 9, 1908.

ANATOMY.

1. Describe superficial and deep palmar arches, giving origin, branches, and external markings.
2. Describe the hip joint. Which is the most common dislocation? Why?
3. Name structures from without inward, that would be cut in section of the arm four inches below shoulder joint.
4. Describe the stomach, giving location, relations, blood and nerve supply.
5. Locate and describe the thyroid gland, giving blood and nerve supply.
6. Name the branches of the aorta from above downward.
7. Describe briefly the cerebrum, giving lobes and fissures.
8. Describe briefly the alimentary canal, naming accessory glands in order.
9. What muscles will be affected by paralysis of seventh nerve?
10. Describe the knee joint.

PHYSIOLOGY.

1. Give the functions of the lungs, describing the various processes.
2. Describe the lymphatic system. Give its functions. How do the lymphatic vessels differ from the blood-vessels?
3. What is meant by reflex action? Give several examples.
4. Define blood pressure. By what means is the caliber of the blood-vessels regulated, and what are the forces keeping the blood in circulation?
5. What three cranial nerves are for special sense? What six are exclusively motor? What three are compound?
6. Give somewhat in detail the physiology of the kidney. (Use a diagram if desired to make your meaning clear.)
7. Describe the various kinds of blood corpuscles, their origin and function.
8. Describe quite in detail the stomach (use diagram). Describe gastric digestion.
9. (a) What are carbohydrates? (b) Proteids? Give examples of each.
10. Name all the organs of elimination.

CHEMISTRY.

1. Define an element, an atom, a molecule, chemical force.
2. Name four functions of a symbol.
3. State the proportions of the chief constituents of the atmosphere. What action is produced on air by animals? By plants?
4. Define an acid salt; a normal salt. Give examples.
5. What are deodorizers; disinfectants; antiseptics? Give an example of each.
6. Enumerate the halogens. Write the formulas for their acids.
7. How may you estimate the total amount of solids in urine by the specific gravity?
8. Give a test for sugar in urine. Determine the quantity by the fermentation test.
9. Name three alkaloidal poisons. Give antidotes.
10. Give chemical name and formula for lunar caustic. Name antidote and describe its action.

PATHOLOGY.

1. Clinically, how does inflammation spread?
2. Give briefly the pathology of fever.
3. What is the difference between septicemia and pyemia?
4. Name four pus microbes.
5. What do you understand by the term karyokinesis?
6. Give points of differential diagnosis between carcinoma and sarcoma.
7. Give the pathology of parenchymatous nephritis.
8. What is a parasite? A saprophyte?
9. Describe the pathology of acute catarrhal gastritis.
10. Give the pathology of osteomyelitis.

BACTERIOLOGY.

1. Explain in detail the Widal reaction. (b) What is its practical application?

2. What do you understand by immunity? (a) Natural? (b) Acquired? Give examples of each.
3. Describe the tetanus bacillus. (a) Where is it found outside the body? (b) How does it enter the body? (c) What conditions are necessary for it to multiply?
4. What are the bacteria usually found in pus? (b) Describe one variety.
5. Give in detail the method of making a bacteriological diagnosis of gonorrhea.

SURGERY.

1. Differentiate burns of the first, second, and third degrees, and give treatment of each.
2. Give diagnosis and treatment in detail of cholelithiasis.
3. Prepare patient, instruments, and your hands for an appendectomy.
4. Give treatment for varicose veins of the leg.
5. Give diagnosis and method of reduction of subglenoid dislocation of the shoulder.
6. Give diagnosis and treatment of fracture of the middle one-third of femur in an adult.
7. Fracture of the base of the skull? (a) Diagnosis. (b) Prognosis. (c) Treatment.
8. Fracture of the clavicle. (a) Diagnosis. (b) Treatment.
9. Diagnosis and surgical treatment of ulcer of the pylorus.
10. How would you treat a contused and lacerated wound of a finger?

PRACTICE AND THERAPEUTICS.

1. Give the physiological action and therapeutics of veratrum viride.
2. Give symptoms and treatment of poisoning by strychnia.
3. Give five (5) coal tar products used in medicine. Give the dose and manner of action.
4. Give the dietetics and treatment of chronic catarrhal gastritis.
5. You are called to see a baby ten months old that is anemic and poorly nourished, but has been apparently well until the day you are called, when it suddenly refused to take its food, was very thirsty, lies with its legs flexed on its abdomen, its finger in its mouth, is crying and peevish, and seems constantly dissatisfied. The mother says that the child vomited several times and has a slight diarrhea. Upon examination you find a temperature of 103° F., a pulse of 130, respirations are somewhat accelerated, the tongue is coated a grayish white, the breath is fetid, and the child has a convulsion while you are there. What is your diagnosis and treatment?
6. Outline an artificial course of feeding for a child four months old in which case it was deemed best not to continue breast feeding, as a diagnosis of tuberculosis had been made in the mother.
7. Give etiology, symptoms, and treatment of tetanus.
8. Write what you can about locomotor ataxia.
9. What is uremia? Name the conditions that cause the same and give symptoms and treatment.
10. Name the most common organic heart lesion, give its diagnosis and treatment.

DISEASES OF WOMEN.

1. Differentiate on the cervix of a woman 45 years old, chancre, beginning carcinoma, endocervicitis, with erosion, and treat a case of the latter.
2. Diagnose and treat acute gonorrheal urethritis, vaginitis, and endocervicitis.
3. Acute vesical cystitis. Symptoms. Diagnosis and treatment.
4. What is subinvolution uteri? Treat a typical case.
5. Give etiology, symptoms, and treatment of condylomata acuminata.

OBSTETRICS.

1. Name the female generative organs, giving their anatomical relations and functions.
2. Give diagnosis of pregnancy at beginning of fourth month.
3. Name the normal head positions in the order of their frequency.
4. Describe your administration of chloroform during labor. What are its dangers, and what its contraindications?
5. Describe the placenta during the ninth month, its usual location and function. Also the funis.
6. Name the varieties of placenta prævia. Give diagnosis, dangers, and treatment in a case of placenta prævia centralis.
7. When would you use forceps in the upper strait? Describe their application.
8. When and how would you use ergot? When is it contraindicated? Name two other oxytocics and the indications for their use.
9. What would you do for rigid os in a multipara?
10. Describe a complete inversion of the uterus following labor, giving symptoms, dangers, prognosis, and treatment.

EYE AND EAR.

1. Give causes, symptoms, and treatment of ophthalmia neonatorum. (b) Of keratitis. (c) When would enucleation of the eye be indicated?
2. (a) Describe the iris. (b) Give diagnosis and treatment of iritis. (c) Of trachoma. (d) In what conditions would mydriatics be indicated?
3. (a) Describe and give treatment of astigmatism. (b) Hypopyon. (c) Purulent dacryocystitis. (d) Synechia.
4. (a) Give diagnosis and treatment of adenoid vegetations. (b) Give indications for mastoid operation. (c) Give treatment for furunculosis of external auditory canal.
5. (a) Give anatomical divisions of the ear. (b) What instruments or appliances are used in a thorough examination of the ear? (c) Give treatment of severe frostbite of external ear.

MEDICAL JURISPRUDENCE.

1. What do you know about rigor mortis?
2. If you were officially summoned to examine the dead body of an adult male person, describe the examination you would probably make to determine the cause of death.
3. How would you determine which was the entrance, and which was the exit, of a bullet wound?
4. If called to see an adult person, apparently dead, how would you determine whether it was a case of syncope, catalepsy, or actual death?
5. What are the legal obligations of a physician in regard to accepting a professional call? And having accepted such call, how may he discontinue attendance on the case without liability for damages?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS, SOUTH DAKOTA.

Examination January 8 and 9, 1908.

ANATOMY.

1. The *superficial palmar arch* is formed by the ulnar artery, and is completed by the ulnar artery anastomosing with a branch of the radial (superficial volar or princeps pollicis). It gives off the four digital branches.

The surface marking is a line drawn transversely across the palm from a point where the web of the thumb joins the palm.

The *deep palmar arch* is formed by the radial artery, and is completed by the radial artery anastomosing with a deep branch of the ulnar. Its branches are the palmar interosseous, perforating, and palmar recurrent arteries.

The surface marking is a line drawn transversely across the palm, one-half inch nearer the wrist than the superficial arch.

2. The most common dislocation of the hipjoint is the *backward dislocation*. This is because: (1) the capsule is thinnest and weakest at its lower and inner part; (2) the cotyloid ligament is weakest posteriorly; and (3) the shallowest part of the acetabulum is below. The head of the bone is, therefore, most likely to find its way in the direction indicated.

3. In *section of the arm four inches below the shoulder joint*, the following structures would be cut: The skin; cutaneous vessels and nerves; fascia; Biceps, Triceps, Coracobrachialis, Deltoid, Latissimus dorsi, and Pectoralis major muscles; brachial and superior profunda arteries; brachial, cephalic and basilic veins; median, ulnar musculospiral, internal cutaneous and musculocutaneous nerves; and humerus.

9. In *paralysis of the seventh nerve*, the following muscles will be affected: Occipito-frontalis, Retrahens aurem, Attollens aurem, Attrahens aurem, Platysma myoides, Orbicularis palpebrarum, Tensor tarsi, Corrugator supercilii, Pyramidalis nasi, Compressor naris, Depressor alæ nasi, Levator labii inferioris alæque nasi, Orbicularis oris, Levator labii superioris, Levator anguli oris, Zygomaticus major, Zygomaticus minor, Risorius, Depressor anguli oris, Depressor labii inferioris, Levator menti, Buccinator, Stylohyoid, and posterior belly of the Digastric.

PHYSIOLOGY.

2. The lymphatic system consists of: lymphatic glands, lymph vessels, perivascular lymph spaces, the lymph canal-

icular system, the pericardial, pleural, peritoneal, and synovial cavities, and the lacteals.

The lymphatic circulation is, strictly speaking, not a circulation at all, since the lymph flows only in one direction, namely, toward the heart. The lymph capillaries take up any excess of the blood plasma which is not required for the nutrition of the tissues. These capillaries consist of a single layer of epithelium, and empty themselves into vessels very like the veins. The lymph vessels are well provided with valves, which are so closely approximated as to give the vessels a beaded appearance. All the lymphatic vessels, except those of the right upper half of the body, empty into the thoracic duct, which terminates in the left subclavian vein, at its angle of junction with the left internal jugular vein. Those from the right upper half of the body discharge into the right lymphatic duct, which, in turn, empties into the right subclavian vein at its junction with the right internal jugular vein.

The forces concerned in the circulation of the lymph are: (1) The pressure of the blood in the blood-vessels; (2) thoracic aspiration; (3) muscular contractions of the voluntary muscles; (4) contractions of the intestine; (5) the action of the valves in the lacteals and lymphatics.

The *function of the lymphatic system* is to provide the tissues with material necessary to their functional activity, growth, and repair; to receive from the tissues their waste products; and to convey the products of digestion and absorption to the blood-current.

The lymph capillaries differ from the blood-capillaries, chiefly, in their larger and very variable caliber and also in their numerous communications with the lymph spaces. The lymph vessels in general have thinner coats than the blood-vessels; and the valves in the lymph vessels are much more abundant than in the veins.

3. *Reflex actions* are involuntary or unconscious movements, due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve.

Reflexes are classified as: (1) Superficial, (2) deep, and (3) visceral.

Example: The patellar reflex consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the ligamentum patellæ is struck; the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire reflex arc, consisting of tendon, afferent or sensory nerve, posterior roots, and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself.

4. *Blood pressure* is the pressure of the blood due to the ventricular systole, the elasticity of the walls of the arteries, and the resistance of the capillaries.

The caliber of the blood-vessels is regulated by the vasomotor nerves (both vasoconstrictor and vasodilator).

The circulation of the blood is regulated in (*a*) *the arteries*, by: (1) the elasticity and tone of the arteries, (2) the force and frequency of the cardiac contractions, (3) the resistance in the capillaries; (*b*) in the *capillaries* it is regulated by: (1) the action of the heart, (2) the action of the arteries; (*c*) in the *veins* it is regulated by: (1) the action of the heart, (2) aspiration of the thorax, (3) the contraction of the muscles, and (4) slightly by the valves in the veins.

5. The three cranial nerves for *special sense* are: (1) olfactory, for smell; (2) optic, for sight; and (8) auditory, for hearing.

Six, *exclusively motor*, are: (3) motor oculi; (4) trochlear; (6) abducens; (7) facial; (11) spinal accessory, and (12) hypoglossal.

Three, *compound*, are: (5) Trifacial, motor and sensory; (9) glossopharyngeal, motor, sensory, and special sense of taste; (10) Pneumogastric, motor and sensory.

7. (1) The *red blood corpuscles* are biconcave discs, about 1-3200 of an inch in diameter; they are nonnucleated, and there are about 4,500,000 or 5,000,000 of them in each cubic millimeter of blood. They are elastic and soft, and their shape is changed by pressure, but is promptly regained on the removal of the pressure. Their color is yellowish. They contain hemoglobin. Their *function* is to carry oxygen from the lungs to the tissues.

(2) The white blood cells are spheroidal masses, varying in size, having no cell wall, and containing one or more nuclei; there are about 7,000 to 10,000 of them in each cubic millimeter of blood. They differ much in appearance, and are divided into (1) small mononuclear leucocytes, or lymphocytes, (2) large mononuclear, (3) transitional, (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named. They are probably formed in the spleen, lymphatic glands, and lymphoid tissues. Their fate is uncertain; it has been asserted that they are converted into red blood cells; they play a part in the formation of fibrin ferment; they are sometimes converted into pus cells. Their *functions* are (1) to serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

(3) There are also *platelets*, which are very small, colorless, irregularly shaped bodies; they are about one-fourth the diameter of a red corpuscle. Their *function* is not determined; it is possible that they take some part in the coagulation of the blood. In number they vary from about 200,000 to more than 500,000 in each cubic millimeter of blood.

9. *Carbohydrates* are substances composed of carbon, hydrogen and oxygen, the two latter being in the proportion to form water; they do not contain nitrogen. *Examples:* Starches and sugars.

Proteids are substances composed of carbon, hydrogen, oxygen, nitrogen; some of them also contain phosphorus, or sulphur. *Examples:* Meat, milk, and leguminous vegetables.

10. The *organs of elimination* are: the kidneys, lungs, skin, intestines, and liver.

CHEMISTRY.

1. An *element* is a kind of substance which cannot, by any known means, be split up into two or more other kinds of substance.

An *atom* is the smallest quantity of an element that can enter into chemical action, or that can enter into the composition of a molecule.

A *molecule* is the smallest quantity of any substance that can exist in a free state.

Chemical force is that power which binds atoms together to form molecules.

2. *Four functions of a symbol.* A symbol represents: (1) The name of the element; (2) one atom of the element; (3) one volume of the element in a gaseous state; (4) the combining weight of the element as compared with hydrogen as unity.

3. The *chief constituents of the atmosphere* are: Oxygen, 21 per cent.; nitrogen, 79 per cent.; and carbon-dioxide, 0.04 per cent.; these are *by volume*.

Animals take up some of the oxygen of the air, and give off carbon dioxide to the air.

Plants take up carbon dioxide and liberate oxygen.

4. An *acid salt* is a salt in which only *a part* of the replaceable hydrogen of the acid has been replaced. *Example:* $NaHSO_4$.

A *normal salt* is a salt in which all of the replaceable hydrogen has been displaced. *Example:* Na_2SO_4.

5. *Deodorizers*, or air-purifiers, are substances which destroy the odorous products of putrefaction. Thus one of the actions of SO_2 is to destroy H_2S.

Disinfectants are substances or agents which restrain infectious diseases by destroying or removing their specific poisons. Some disinfectants are germicides, as chlorine; others act by dilution or removal without being germicides, as soap and water and fresh air.

Antiseptics are substances which prevent or restrain putrefaction. They are either germicides, which act by destroying the bacteria causing putrefaction, or agents which, without destroying the vitality of these organisms, render the conditions unfavorable for their development. Thus cold and the aluminium salts are antiseptic but not germicidal.—(From Witthaus' *Essentials of Chemistry*.)

6. The *halogens* are: Fluorine, chlorine, bromine and iodine. Their *acids* are: Hydrofluoric, HF; Hydrochloric, HCl; Hypochlorous, HClO; Chlorous, $HClO_2$; Chloric, $HClO_3$; Perchloric, $HClO_4$; Hydrobromic, HBr; Hypobromous, HBrO; Bromic, $HBrO_3$; Perbromic, $HBrO_4$; Hydriodic, HI; Hypoiodous, HIO; Iodous HIO_2; Iodic, HIO_3; Periodic, HIO_4.

7. The last two figures of the specific gravity multiplied by 2.33 gives, in normal urine, approximately the amount of total solids in a thousand parts of urine. *Example:* Specific gravity is 1.017; $17 \times 2.33 = 39.61$ grams of solids in 1,000 c.c. of urine.

8. *Test for sugar in urine:* The urine should first be tested for albumin. If this be present, it should be removed by heating the urine to near the boiling point, and filtering from the coagulum.

Fehling's test: Place in a test-tube a few c.c. of the liquid prepared as stated below, and boil: no reddish tinge should be observable, even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of *traces* of glucose, only

a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out.

[The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c.; and Solution II of 130 gms. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

Quantitative determination by the fermentation test: The sp. gr. of the urine is carefully determined at 77° F.; yeast is then added, and the mixture kept at 77° F. until fermentation is complete; the sp. gr. is again observed, and will be found to be lower than before. Each degree of diminution represents 0.2196 gram of sugar in 100 c.c. of urine.—(From Witthaus' *Chemistry.*)

9. *Three alkaloidal poisons, with antidotes:* Atropine; antidote, morphine or tannin. (2) Morphine; antidote, potassium permanganate, or tannic acid, strychnine, and caffeine. (3) Cocaine; antidote, amyl nitrite.

10. LUNAR CAUSTIC. *Chemical name:* Silver nitrate. *Formula:* $AgNO_3$. *Antidote:* Solution of sodium chloride. It acts by decomposing the silver nitrate and forming the insoluble silver chloride:

$$AgNO_3 + NaCl = AgCl + NaNO_3.$$

PATHOLOGY.

1. Inflammation spreads by: (1) the bloodvessels; (2) the lymphatics; (3) continuity of tissue.

3. *Septicemia* is a condition of acute general infection due to the presence of pyogenic bacteria in the blood.

Pyemia is the condition of general infection when metastatic abscesses are formed.

Septicemia begins with a rigor, followed by a rise of temperature up to about 104° F., which remains constant. The pulse is weak and progressively rapid; there is anorexia and constipation, which is followed by diarrhea; the urine contains albumin; the temperature may become subnormal. There are no repeated rigors and no secondary (metastatic) abscesses. *Pyemia* begins with a rigor, which may last for half an hour, and is repeated every one or two days. The temperature rises as in septicemia, but rapidly falls, and at the same time the patient suffers a profuse perspiration. The pulse is weak and rapid; there is anorexia; and there may be delirium, with jaundice and signs of abscesses in the lungs, joints, etc. In pyemia there are repeated rigors and secondary abscesses.

4. *Four pus microbes:* Streptococcus pyogenes; Staphylococcus pyogenes aureus; Staphylococcus pyogenes albus; Staphylococcus pyogenes citreus.

5. By *Karyokynesis* is understood indirect cell reproduction, preceded by the complicated cycle of changes in the cell nucleus.

6. *Carcinoma* occurs most frequently after middle life, is derived from the epiblast or the hypoblast; possesses a stroma, in which are both blood-vessels and lymphatics; metastasis occurs by the lymphatics.

Sarcoma occurs most frequently before middle life, is derived from the mesoblast; it has no stroma and no lymphatics; metastasis occurs by the blood-vessels which are in contact with the cells.

8. A *Parasite* is an organism which lives upon or within another (living) organism.

A *Saprophyte* is an organism which lives upon dead organic matter.

BACTERIOLOGY.

2. *Immunity* is the power of resistance of cells and tissues to the action of pathogenic microorganisms. Immunity may be either natural or acquired.

Natural immunity is that power of resistance, natural and inherited, and peculiar to certain groups of animals, but common to every individual of these groups.

Acquired Immunity is this resistance acquired (1) by a previous attack of the disease, or (2) by the person being made artificially insusceptible. The conditions which give immunity are: (1) a previous attack of the disease; (2) inoculation with the specific microorganisms in small numbers or of diminished virulence, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

Examples.—The rat is *naturally immune* to anthrax; the white mouse is *naturally immune* to infection with bacillus mallei. *Acquired immunity* is seen in the immunity from smallpox after vaccination, or after having suffered from an attack of the disease.

3. The bacillus of tetanus is characterized by its peculiar spore, formed at one end of the bacillus, and giving it the appearance of a pin; it is purely anaërobic, and cannot be developed at all in the presence of oxygen. It generally comes from the soil, and is found in penetrating wounds. It appears in two forms, the spore-bearing form, as described above, and the vegetative form, which is a short bacillus with rounded ends, and which may occur singly or in pairs, or may form long filaments. It grows in gelatin stab cultures in the middle of the medium, and the colonies look something like a fir tree; its growth is slow, and a disagreeable odor is at the same time emitted. In bouillon, it grows near the bottom of the tube, and produces gases.

4. (*a*) The *bacteria usually found in pus* are: Staphylococcus pyogenes aureus, Staphylococcus pyogenes albus, Staphylococcus pyogenes citreus, Streptococcus pyogenes; also sometimes the pneumococcus, gonococcus, B. coli communis, B. pyocyaneus, B. typhosus, and B. epidermidis albus.

(*b*) The *Streptococcus pyogenes* is a micrococcus, of spherical shape, and arranged in chains of about thirty or forty cocci (in liquid media) but the chains are much shorter in solid media. Each coccus is about one-half to two mikrons in diameter. It is not motile, does not form spores, does not liquefy gelatin, and stains readily with the ordinary anilin dyes, and by Gram's method.

5. On a cover-glass make a smear with the discharge as thin as possible, and let it dry in the air; cover it with a freshly-made solution of anilin-oil-gentian-violet for one or two minutes; wash it in distilled water; leave it in Gram's solution for two minutes; wash it in 95 per cent. alcohol until decolorized; wash it in distilled water; counterstain with a dilute carbolfuchsin without heat, or with a saturated aqueous solution of Bismarck brown; wash in distilled water, dry with filter paper, mount, and examine with an oil-immersion lens. The gonococci will appear as *diplococci within the leucocytes*, which have been *decolorized by Gram's stain*, and have taken the counterstain.

PRACTICE AND THERAPEUTICS.

2. The *symptoms of poisoning by strychnine* are "a sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm, or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes; and death in from five minutes to six hours, usually within two hours."

Treatment.—"The convulsions are to be arrested or mitigated by bringing the patient under the influence of chloral or chloroform as rapidly as possible; the stomach is to be washed out, and the patient is to be kept as quiet as possible." (Witthaus' *Essentials of Chemistry.*)

DISEASES OF WOMEN.

2. ACUTE CYSTITIS. *Symptoms.*—Frequent urination, with tenesmus and a burning sensation in the urethra, later on pain in the bladder; the urine may be alkaline and turbid, and may contain blood, mucus, bacteria, pus, and epithelial cells. Chills, rapid pulse, fever, and headache may also be present.

Treatment includes: Rest in bed; administration of plenty of cold water or milk, diuretics, bland and mild foods, laxatives, hot sitz baths or vaginal douches, irrigation of the bladder with antiseptic solution followed by solution of nitrate of silver.

OBSTETRICS.

3. L.O.A.; R.O.P.; R.O.A.; L.O.P.

9. The *management of a rigid os uteri* consists in: The administration of chloral hydrate, gr. xv., three doses being given at intervals of about twenty or thirty minutes; hot vaginal douches directed against the anterior lip of the os; if these methods do not suffice, it may be necessary to give an anesthetic, forcibly dilate the cervix, and deliver by forceps; the cervical laceration, if any, must be repaired.

EYE AND EAR.

1. (*a*) OPTHALMIA NEONATORUM. *Causes.*—The gonococcus or some other pyogenic microorganism; the secretions of the mother contain the infecting agent, and transmission may occur directly during parturition, or indirectly by the fingers of physician or nurse, cloths, instruments, etc.

Symptoms: Swollen eyelids, with copious purulent discharge; ulceration of the cornea may ensue.

Prophylaxis.—Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a one or two per cent. solution of nitrate of silver, immediately after birth.

Treatment.—Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a two per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must

be isolated, and all cloths and compresses used must be burnt.

(*c*) The *indications for enucleation of the eye*, are: "(1) Injuries of the ciliary region when the eye is completely blind, or the traumatism so extensive that the form of the eyeball cannot be preserved; (2) traumatic iridocyclitis, to prevent or cure sympathetic ophthalmia: (3) severe pain in a blind eye; (4) irido-cyclitis, phthisis bulbi, and glaucoma, when accompanied by severe pain or inflammatory symptoms, and when the eye is blind or is certain to become so; (5) malignant tumors, either intraocular or epiocular, if they cannot be removed with retention of the eyeball; (6) anterior staphyloma, if the eye is blind, troublesome, and disfiguring; (7) panophthalmitis, after the suppurative stage is passed; (8) foreign bodies in the eye when they cannot be removed and cause irritation, or the eye is blind." (May's *Diseases of the Eye.*)

MEDICAL JURISPRUDENCE.

3. (*a*) In gunshot wounds by *soft lead bullets*, the *wound of entrance* is often smaller than the ball (skin stretched at the moment of impact and contracted after perforation); it is depressed, and the edges are contused and inverted, and if the weapon is fired within ten feet usually are blackened from powder and contain powder grains. If the wound is much larger than the bullet, it means that some foreign body has been carried in.

The *wound of exit* is everted, "triangular, linear, or stellate," and much larger than the wound of entrance.

(*b*) In gunshot wounds by *hard lead, or steel bullets*, the *wound of entrance* is usually as large as the ball, the skin may be split or may be perforated, and foreign bodies are not carried by the ball into the tissue.

The *wound of exit*, if not in the region of explosive action, may be a little larger or a little smaller than the bullet, but is not noticeably larger than the wound of entrance. If within the area of explosive action, the wound of exit is much larger than the wound of entrance, and is irregular and everted. (From Da Costa's *Modern Surgery.*)

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.		
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan.	5
Arizona*	Ancil Martin, Phoenix	Phoenix	Oct.	5
Arkansas*	F. T. Murphy, Brinkley	Little Rock	Oct.	13
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	Los Angeles	Dec.	1

Contagious Diseases. Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City for the week ending September 19, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	531	140
Diphtheria	206	28
Measles	103	5
Scarlet Fever	112	6
Smallpox	—	
Varicella	9	
Typhoid Fever	168	18
Whooping Cough	23	5
Cerebrospinal Meningitis	8	6
Malarial Fever	—	—
Totals	1161	208

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending September 19, 1908:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.
Indiana, Fort Wayne	Aug. 16–22	1	
Kansas, Wichita	Aug. 31–Sept. 5	1	
Michigan, Saginaw	Aug. 31–Sept. 5	6

THE SERUM TREATMENT AND THE PROGNOSIS, UNDER VARIOUS FORMS OF THERAPY, OF CEREBROSPINAL FEVER.*

By HENRY KOPLIK, M.D.,
NEW YORK.

It is too often apparent in considering the methods of therapy of any disease that we sometimes lose sight in the presence of some exceedingly favorable results of the natural course of the affection, and in no disease is this more common than in cerebrospinal meningitis. This disease, as Osler has pointed out, resembles very closely in its behavior pneumonia. It is true the affection occurs sporadically and in epidemics. In the sporadic form the disease occurs at times when there cannot be said to be any prevalent epidemic. That is, a limited number of cases will appear in a city in places removed from each other, and having no connection with each other. By epidemics of meningitis we understand distinctly the occurrence in larger numbers of cases in groups, and in this disease, especially in densely populated quarters. In the sporadic form cerebrospinal fever is an affection at times, so mild as to give few symptoms of a critical nature. At other times in the sporadic form the disease takes on a severer type, and then the picture closely resembles what is seen in epidemics of the disease. In the absence of epidemics the cases of crebrospinal meningitis which have come under our control have impressed us with certain characteristics, or, rather, the absence of certain characteristics which we see during the times of epidemics. I have seen sporadic cases so mild that the intermittent or remittent febrile symptoms, headache and drowsiness, were the only symptoms which led us to think of the diagnosis. In the sporadic forms we have the rigidity, the hyperesthesia, the presence of the Kernig reaction, and in occasional cases the herpes. There is also delirium and the presence of gradually increasing hydrocephalus, as evinced by the so-called Macewen sign. I think any one who has passed through an epidemic of cerebrospinal meningitis will admit that in the sporadic cases we rarely meet the severer symptoms of the disease, such as the sudden and abrupt onset of unconsciousness, the petechiæ or diffuse hemorrhages so frequent in the epidemic forms of the disease, and the paralysis which appears very early in the epidemic forms. In fact, in an epidemic it is not infrequent to be called to the bedside to see a child who within a few hours has become unconscious and absolutely paretic to an extent as not even to show the rigidity and the Kernig sign, which is seen and gradually develops so classically in the sporadic cases. In the sporadic cases we rarely see those excessive hemorrhages in infants which are seen in the epidemic form.

It must, therefore, be admitted that though on the whole the symptomatology of the sporadic is exactly similar to that of the epidemic form of the disease, the sporadic form runs a much milder course. As we analyze both forms more deeply, we find that the purulent exudates are more frequently obtained in the epidemic than in the sporadic cases of the disease. Lumbar puncture in the sporadic cases exceptionally reveals a purulent fluid at the outset. It is true a certain proportion of the sporadic cases are purulent, but not to the extent as is seen in the epidemic forms of the disease

In a word, cerebrospinal meningitis of the meningococcic type very much resembles pneumonia as it is seen in adults in the sporadic and epidemic forms. Any one who has lived through an epidemic of pneumonia must admit that the picture is a violent and a virulent one in its type, and so with meningitis. We have the same infection, but in the epidemic form it is of a violent and virulent type, and with children the younger the subject the more fatal the disease.

These facts are so self-evident that it is surprising they are so constantly lost sight of, and that in considering any mode of therapy we do not stop not only to consider the violence of the infection, but the age of the patient. For this reason I have thought it would be useful for every one at this time to get a picture of the natural history and prognosis of cerebrospinal meningitis, especially if the experience which reflects the prognosis extends over a long period of time and the methods of treatment have been uniformly the same and carefully carried out in all details through a number of years.

Taking up the sporadic form of meningococcic cerebrospinal meningitis, I have been fortunate to have at my disposal the records of cases treated since 1899 up to the epidemic years of 1904-1905. We first began the systematic treatment of cerebrospinal meningitis in 1899. This consisted in the first place of a careful study of the symptoms and the performance of lumbar puncture repeated as often as we found the symptoms to warrant it. That is, a patient suffering with cerebrospinal meningitis would come in with mild symptoms. If there was delirium, high fever, with the development of the signs of fluid in the ventricle as evinced by the Macewen sign, lumbar puncture was performed. After such a puncture, if the symptoms did not abate, the fever continued, as well as the delirium and the Macewen sign persisted, proving that there was a continued hydrocephalus, the patient was again punctured. In this way some patients were punctured two, three, four, and five times, as necessity called for. During 1899-1900 we had eight cases, all proving by lumbar puncture to have been meningococcic in type. During 1901, 1902, and 1903 there were thirteen cases, thus giving us a total of twenty-one sporadic cases. Of these sporadic cases eight died, a mortality of 38 per cent.; of these eight which proved

*Read before the American Pediatric Society, May, 1908.

fatal, six were below one year of age, thus showing that in the sporadic form the disease was most fatal among the infants below one year of age, and equally so below two years of age. If we could deduct from the total number of twenty-one cases those which were below one year of age, we would have fifteen cases, with only two deaths, a mortality of 13 per cent. From this a mere glance will tell us that meningitis of the meningococcic type in its sporadic form is a comparatively mild disease.

I say this with a certain amount of confidence, although the number of cases is limited, for we are now having a certain number of sporadic cases which seem to duplicate our experience in these years. On the other hand, in sporadic meningitis we have been fortunate by methods of therapy, which consisted mainly in the systematic application of lumbar puncture repeated at intervals, in obtaining recoveries even below one year of age. Two infants of this tender age recovered of these twenty-one cases, and two recovered between the ages of one and two years. It is in the sporadic cases especially that we occasionally see after one lumbar puncture the temperature drop and convalescence practically inaugurated, the temperature not rising subsequently to any extent. This phenomenon is not so frequent nor so persistent as is seen under the new method of therapy, that of serum. Under serum therapy there are more cases which act in this manner than under previous forms of therapy.

Taking up the epidemic years of 1904 and 1905, the history of the disease is a more violent one. Among the cases are some which died within a few hours after admission to the hospital. This, it is understood, is the exception in the sporadic cases, but not uncommon in epidemic cases. Here the picture of the disease is more of sthenic type, the symptoms being developed in their most florid form.

The first epidemic year was 1904. There were thirty-nine cases and twenty-one deaths, a total mortality of 53 per cent., and of these twenty-one deaths thirteen were below two years of age. If we consider the unimproved cases of these thirteen as not fatal, eleven died, but I would prefer to consider these fatal cases as they were discharged from the hospital in a marantic condition, with an incurable and increasing hydrocephalus, so that from a curative standpoint the mortality was practically 100 per cent. Some of these infants were four months of age, six months of age, showing the tender age of the patients. Deducting these thirteen cases from the total of thirty-nine would leave twenty-six cases above two years of age, of which nine died, a mortality of 34 per cent.

In 1905 there were thirty-five cases in my service of which seventeen died. In none of these cases have we included any which have not been distinctly proven by lumbar puncture to be of the meningococcic type. There was thus in this year a total mortality of 48 per cent. Of these seventeen deaths, however, ten were below two years of age, and in them it might be said that the mortality was fully 100 per cent., for if seven died and three were simply unimproved, that is, developed either hydrocephalus or marasmus of an extreme type hopelessly incurable, we can scarcely speak of a cure, therefore these three were no better than fatal cases, so that although there was a mortality of 70 per cent., from the standpoint of success in therapy the mortality was practically 100 per cent. below two years of age. If we deduct those cases which died below two years of age from the total mortality of seventeen, and from the total number of cases which were admitted during this epidemic year, we are left a mortality of seven deaths in twenty-five cases, that is, 28 per cent. It is thus seen that it would be quite unfair to consider any mortality in this year of the violent type without considering the tender age of some of those affected in order to get a definite idea of the picture. It may be said in addition, the ages of these children ranged from four months to twelve years of age. Thus of the two epidemic years of 1904 and 1905 we had fifty-one cases above two years of age, with a mortality of 31 per cent., and, considering the patients below two years of age in the mortality, there was a total mortality of 50 per cent. This includes patients on whom there was only an opportunity to make one lumbar puncture, and in whom death occurred within a few hours after admission to the hospital. Nothing has been excluded for the sake of statistics, but the moribund cases have been included in this statistic with the favorable cases. We had twenty-three cases in these two years below two years of age, of which 78 per cent. died outright, and the remainder were unimproved—that is, those who were discharged with incurable hydrocephalus, idiocy, and marasmus, and which might be considered as practically fatal sooner or later.

From the study of these two sets of statistics one of the sporadic cases of cerebrospinal meningitis and the other of the epidemic form, we see that in the sporadic cases we have succeeded in saving by simple lumbar puncture four children below two years of age; in the epidemic cases we have succeeded in not saving any. When I say four cases recovered, I mean complete and actual recovery, as far as can be judged from the clinical standpoint. No such cases occurred in the epidemic years. On the other hand, if we deduct from our statistics the cases below two years of age, both in the epidemic and sporadic forms of the disease, we find that in the sporadic form we had fifteen cases, with a mortality of 13 per cent., and in the epidemic form we had fifty-one cases, with a mortality of 31 per cent.

With this history of the disease, we can approach with a certain amount of satisfaction a form of therapy which will hold out an improvement even on these statistics. We can scarcely ask an annullment of mortality. There will always occur cases in either form of the disease which therapy will never reach, no matter how brilliant the conception of the therapy. We see this in diphtheria. No one will deny the great blessing to mankind that the serum treatment of diphtheria has come to be. We have even believed that certain severer forms of diphtheria are becoming less frequent than before the serum therapy. The severer laryngeal types are not so common to-day, even in epidemics of the disease, and this is certainly a great gain. In other words, by the constant application of a form of therapy conceived on a logical basis of antagonism to the bacteria attending the disease, it seems that the actual poison has been diluted and the picture of the disease is a much milder one to-day than before the application of the serum therapy, and thus it may be of other diseases.

Considering cerebrospinal meningitis treated by serum we have to offer thirteen cases of the disease occurring in one service, and treated with the exception of the application of the serum, in the identical manner that the cases were treated which have just been spoken of. That is, they were systematically punctured, they were repeat-

edly punctured, they were punctured only on indications as above detailed in the epidemic and sporadic years, but when punctured they received the serum. They received the serum under conditions exactly similar to those of cases occurring years ago, at a time when the serum did not exist. Our serum cases were thus under the same identical régime as the other cases, and we think that this is of decided advantage not only to the patients, but to others.

It makes quite a difference in the application of such a therapy how such a therapy is applied. A therapy applied by inexperienced hands, no matter how brilliant the therapy, is not given the same chance as in the hands of those who are skillful. We make this remark simply in passing, because any form of therapy will at first labor under a great disadvantage for lack of skillful application and method.

It may not be amiss here to outline very briefly our method of giving the serum to patients. No patient is punctured in my service in cerebrospinal meningitis unless there is distinct indication for that puncture. In this way I impress those around me that I do not believe in the dictum that the earlier the puncture the better. This dictum, I think, is rather mechanical on account of the panicky feeling to do something immediately which it engenders, and does harm to the patient. To be punctured, a patient must show symptoms of pressure and indications of cerebrospinal fluid. There must be not only delirium and sopor, but distinct signs of increase of fluid in the ventricles of the brain, as shown by percussion of the skull. When we get the so-called Macewen percussion note, however slight, in a patient who evinces the symptoms of cerebrospinal meningitis, we proceed to puncture. The puncture is carried out strictly according to Quincke's injunctions. We puncture in the median line in children and adolescents. We withdraw the fluid until we think the pressure is approximately normal in the rachidian space. We then introduce the serum, not with a syringe, but with a funnel. We have found that the funnel as advised by Quincke, a small funnel made of glass capable of holding about 20 c.c., is the best method of introducing the serum, or, for that matter, any fluid into the subarachnoid space, and saves the patient from any accident which might result from the use of a syringe. The pressure exerted by a syringe at all times against the respiratory and vascular pressure is certainly not as gentle a mode of introduction of serum or as safe as allowing the serum to flow into the canal. Thus no traumatism can possibly result, and the fluid finds its way against the negative pressure with the greatest of facility. We repeat the puncture if, after having punctured a patient and introducing the serum, we find that the symptoms do not abate and that the hydrocephalus has either persisted or returns. The temperature is scarcely a guide, but, rather, the general condition of the patient, and especially the presence or absence of hydrocephalus. In this way we think we have made the ideal procedure for the patient.

We have a record now of thirteen cases of varying severity, cases which I must consider sporadic cases, but one or two of which approached in severity what we see during epidemics exclusively, the foudroyant symptoms, the hemorrhages, the rapid collapse and sinking of the patient at the start of the disease. I mean the severity of the symptoms gradually increased so that, as in one case, it was five days before coma or sopor intervened.

The ages of the patients treated varied from three and one-half months to five and one-half and eleven years; three were below one year of age, and three were two years of age or younger. Of those below one year of age one was discharged cured at ten months of age. The others died. Of those from one year to two years of age, two of fifteen months, and one of two years, respectively, were cured; the remaining patients recovered.

In those children below one year of age who died, the youngest, three and one-half months of age, had been two weeks ill on admission, but was not by any means unconscious. The child received from 100 to 125 c.c. of serum. The temperature continued remittent, and was not in the least affected by the injections or punctures. The other case was admitted to the hospital twenty-two days after the onset of the disease, received four punctures and 66 c.c. of serum. The temperature could not be judged as being affected by the punctures in any way, as it was normal on admission. The child died a day or two after admission, and it is to be regretted that in both of these cases we did not get them at an earlier stage of the disease, as we cannot judge what would have been the effect had we received them at an early period. The first punctures in both cases were, of course, made immediately upon admission. The infant ten months of age which recovered, was admitted fifteen days after the onset of the disease, with a temperature of 104°. A turbid fluid was obtained, and the child received 35 c.c. of serum. The temperature dropped from 104° to 98.8°, and the child was discharged cured clinically.

Of the other cases below two years of age and two years, the first punctures were made immediately after admission, and they had been ill from seven to twenty-three days. One was discharged as cured, but inasmuch as there was hydrocephalus present on discharge of the patient, I think it, being a posterior basic case, from a clinical standpoint cannot be said to have been completely cured. I would simply call it improved.

Of the patients above two years of age the time of illness on admission to the hospital varied from five days to fifteen days. They all received serum varying from 15 to 30 c.c. at each puncture, and some of them had as many as four punctures before the disease was considered under control. The fluid in most cases after the first puncture cleared up gradually, and in one case it is stated after the second puncture the cultures were sterile, and so with the third puncture, and in some cases after the fourth puncture. But it must be noted in spite of this fact the children were sick enough to be punctured not only on account of the run of the temperature, which was unchanged by the punctures, but the persistence of the hydrocephalus. This was especially marked in a boy of three years of age. The first puncture showed a white, cloudy fluid. Four punctures were made in this case, until the temperature would drop, and in all three punctures subsequent to the first the cultures and smears remained sterile. This should prove conclusively that the sterility of a fluid has very little to do with the clinical procedure in a given case, and I may say that in the epidemic a child mortally ill with meningitis would yield a fluid which was even cloudy, and the smears and cultures for some reason would remain sterile, and a subsequent puncture would show that there were meningococci present both in smear and culture, so that we have yet to learn a great deal as to why certain fluids are culturally

sterile in a patient in whom a subsequent fluid will show meningococci, and also that the sterility of a fluid is not an indication that the patient necessarily does not need further puncture irrespective of serum.

The temperature after the injection of the serum in some of these cases fell by crisis from 104° to 98°. In one case it fell from 103° to 99° by lysis, and in one remaining case the puncture had no effect, and only fell and rose to a varying extent after the injections until either cured or fatal issue resulted. The amount of serum injected with punctures varied, and we can say in a general way that the amount of serum introduced equaled that of cerebrospinal fluid withdrawn from the patient. Some patients received one puncture, others as many as four, according to the necessities of the case.

The sickest child treated with the serum was a little girl four and one-half years of age. Hers was a case which approached in the picture, as nearly as we had seen in sporadic cases, the epidemic type of the disease. I saw her at her home. She was absolutely unconscious, paralytic on the right side of the body, and had a conjunctivitis as a result of her affection, with purulent discharge. She suffered from a double pneumonia, and had all the marked symptoms of cerebrospinal meningitis, with the exception of the hemorrhages. I gave, as my duty dictated, a grave prognosis, but advised immediate puncture. She was removed to the hospital, a great distance, and was immediately punctured and an injection of the serum introduced. In this case three punctures were made. It cannot be said that the temperature remained down for any length of time after any puncture, except after the second or third puncture. After the first puncture the temperature dropped from 104° to 98°; within thirty-six hours it rose again, and then after a second puncture it fell from 102° to 99° in twenty-four hours, and then rose again, and after the third puncture it fell gradually to 100°, and then after a few days to 99°. This child gained consciousness after the first puncture; the hydrocephalus, however, persisted, and she was repeatedly punctured until she became rational after the third puncture. The second puncture was made two days after the first puncture; the third puncture was made four days after the second.

I have thirteen patients thus far treated with the serum, two of which are under observation, two of which died; the remainder recovered with the exception of one, which was discharged improved. A résumé of these cases will be given by Dr. Flexner in his article on the serum, and they are to be found under the heading of cases coming from the Mount Sinai Hospital.

I think it would be rather premature and unfair in every way to draw any conclusions as to the serum until we have seen a larger material and until we have tried it in an epidemic of the violent type, such as we passed through in 1904 and 1905. On the other hand, it may be said that the serum of Flexner not only makes a very favorable impression, but is certainly a factor which cannot be excluded from the therapy of cerebrospinal meningitis, no matter what our subsequent conclusions may be. It certainly does appear that with the serum as we perfect it we may have an improvement in the percentage of recoveries. It is hard to say sincerely whether taking the cases I have treated I shall continue to have the same good fortune to save all but two cases of thirteen. Even if the cases I have lost were below one year of age, judging from the results obtained elsewhere, we may still meet with cases which we cannot save by the serum, and it would certainly be very unreasonable to expect a continuance of such a very high percentage of recoveries as we have just shown.

SOME MISTAKES WHICH MAY PREVENT THE BEST RESULTS OF THE URIC-ACID-FREE DIET.

By ALEXANDER HAIG, M.A., M.D., OXON., F.R.C.P., LONDON.

PHYSICIAN TO THE METROPOLITAN HOSPITAL AND THE ROYAL HOSPITAL FOR CHILDREN AND WOMEN.

To get free from disease which is occasioned in whole or in part by uric acid, it is not merely necessary to cease swallowing uric acid or xanthin, but some means must also be found for getting rid of the stores or accumulations of these substances already in the body. This is necessary in troubles of the gout or rheumatism class, because there can be no peace or comfort in the tissues, while the joints, fibrous tissues, muscles, and fasciæ contain more or less considerable quantities. And for the same reasons it is always necessary to guard carefully against any accumulation of such stores by retention.

Then even getting these deposits into solution may increase the local irritation at first, till the accumulation has been completely dissolved and removed, for during this resolution the urate is for a time in the same condition (*i.e.* colloid urate in suspension) as it was when causing the first irritation in the joint (acute arthritis). The deposit of biurate is a later stage of the process, and with this deposition of insoluble biurate all iritation ceases. Yet when a solvent (alkali) begins directly or indirectly to get this urate into solution, local irritation begins once more. An alkali may act directly on the biurate, getting it into solution or colloid form (as may be seen by observing the action of alkali on uric acid under the microscope), or indirectly, by sweeping urate out of the body by the kidneys, thus rendering the body-fluids poor in urate, so that they are no longer saturated with it; and these fluids will then themselves (as shown by the late Sir William Roberts) begin to take up urates from the deposits. For this reason the blood of those who live on the uric-acid-free diet is nearly always in a condition to take up urates from the deposits, for it is only rarely saturated with these substances. Hence the uric-acid-free diet itself may cause some increase of joint pains when it is first begun, and this increase of pain is not to be looked upon as a bad sign but as a good one.

In either case solution whether by diet or by alkali may occasion some increase of local irritation or pain, and unless its causation and the fact that it is a good sign are borne in mind, the treatment may be unnecessarily blamed and given up.

For this reason potatoes and other vegetables containing much alkali are often said to be things which the gouty must carefully avoid for fear of increasing their pain. And no doubt on ordinary diet this is quite true, for it is no use stirring up old deposits and getting them into solution, unless this is to be part of a general clearance of urates, aided by a diet which at least does not introduce fresh quantities; so that the gouty had better avoid potatoes unless they are going to do the thing thoroughly.

It is also necessary to get clear of deposits in the case of the circulation troubles (headache, epi-

lepsy, and depression) for so long as there is plenty of urate in the body available for solution, so long will the blood be liable to be flooded with this substance and the attacks of these troubles will be more or less frequent.

It follows that the uric-acid-free diet must be modified, at least to some extent, and in the early stages of its use, according to the nature of the case with which we have to deal; whether it is one of arthritis and retention or collemia and depression, or again whether the patient is strong and well-nourished with good blood, or weak, anemic, and dyspeptic; and very many of the mistakes about which I am speaking are due to neglect of these points in practice.

The object of the uric-acid-free diet is to get as free as possible from uric acid, to reduce introduction, which on ordinary diet often amounts to eight or ten grains per day, down to nothing. As a result of this we have only to deal with some ten to thirteen grains of daily formation, and so we reduce the daily turnover of uric acid from twenty-three grains to thirteen.

Now we must never forget that the ideal of uric-acid-free diets is that of the lower classes in the poor rural portions of England, Scotland, and Ireland as it was sixty, eighty, or a hundred years ago, before the great general invasion of flesh and tea, which, especially in the last thirty years, have become so much cheaper and more widely used. This diet consisted of bread with wheat or barley meal and cakes made from these, some milk and cheese, and some vegetables. There was no fruit in winter and only a little home-grown in summer, but some home-grown vegetables were available most of the year round. Milk and cheese were then relatively cheap in the country, as there were in those days but few facilities for drafting them off to the large towns, while in these days of easy transit town prices rule more or less in the country, and milk is no longer the cheap food for the poor which it used to be. The nourishment of this diet was got out of the bread, meal, milk, and cheese, all practically uric-acid free, and the alkaline vegetables with manual labor kept the blood alkaline and allowed all the uric acid of formation to pass freely out of the body. These people therefore lived on the best form of uric-acid-free diet obtainable in this country, and were and remained uric-acid free because labor and vegetables aided excretion and there was no fruit out of season to cause retention; yet they had plenty of nourishment, which labor and a hearty appetite enabled them to take freely, and they were thus strong, hearty, and healthy.

If we bear this ideal constantly in mind we shall easily see to what extent other modifications of the uric-acid-free diet differ from it and the probable effects of these differences, for it is obvious that, even though we keep the daily turnover of uric acid at thirteen grains a day, there may still be some excess of uric acid in the body, if the whole of the thirteen grains is not excreted each day as it is formed. If on Monday, Tuesday and Wednesday only eleven grains are excreted, then on Thursday, Friday, Saturday, or some later day six grains will be available to pass through the blood and help to produce an attack of some collemic trouble as they pass. And these same six grains may at the time of their retention have produced more or less pricking and shooting pains in the joints, fascia, or other fibrous tissues; so that it is possible even on a completely uric-acid-free diet to suffer from arthritis on the one hand or collemic trouble on the other, if the diet, though uric-acid-free, is unsuited to the climate, house, clothing, exercise, nature of soil and water, etc., of the place where the patient lives: that is to say if any of these things, acting with a relatively unsuitable diet, are permitted to cause retention. Thus the uric-acid-free diet must vary with the season, being more alkaline in winter and less alkaline in summer, more alkaline the more sedentary the patient's life and more laxative the harder the water.

There is but one object for all these variations, namely to approximate to the above ideal of life and food, and like that ideal to prevent retention or render it improbable under ordinary conditions. The peasant of old times was uric-acid-free because (1) his diet was so; (2) it contained a fair quantity of potato and vegetable; (3) it contained but little fruit and that only when in season in the place where he lived; (4) bodily labor kept his blood highly alkaline by eliminating acids in perspiration; (5) labor gave a hearty appetite, hence he could eat bulky foods freely and was therefore strong and well-nourished; (6) the bulky food prevented constipation, which is always a cause of relatively high acidity and retention in those who suffer from it. Constipation, as I have elsewhere pointed out, raises acidity by increasing the absorption of acids from the large intestine; hence the twofold bad effect of hard water, for urate of lime is insoluble, and the constipation, which lime also produces, aids retention by diminishing the alkalinity of the blood.

How very different from this ideal is the position of the town dweller, office worker, or bookworm of to-day who wishes to attempt the uric-acid-free diet, how many difficulties are obviously in his way? He is full of uric acid from his old diet, he cannot take bulky foods like bread-stuffs and vegetables, he only gets exercise for an hour or two twice or thrice a week, hence his appetite and only too often his digestion, as well, are poor. He commonly suffers from constipation, which acts with diminished exercise in diminishing alkalinity and favoring retention; moreover he has acquired along with his meat-eating more or less of the stimulant habit, and so on the new diet he at once goes in for the stimulating acids of fruit and will take these to excess and produce retention with them if not prevented. He feels that he must have something to replace his lost stimulants (flesh and tea).

Now I do not wish to be understood as saying that, in the early stages of diet change and for those who suffer much from depression and collemia while changing, a little extra fruit is a bad thing and one to be always avoided. In such cases it is often very useful, and it is better to use a litle fruit in place of a drug; but it must be understood by all that if this is persisted in, and continued too long, if the practice of stimulation is merely carried on by fruit instead of by tea, this will prevent on the one hand the complete clearing out of deposits necessary for the cure of rheumatism and gout, and on the other will provide or increase accumulations some of which may at any time pass into solution in the blood, causing from time to time collemia and its results. Such patients suffering from collemic troubles and starting off with stimulation and retention by fruit, cold, bracing climate, acids, etc., may be much better for six, twelve, or even eighteen months.

and then all their troubles will return and the diet may be said to have failed.

It is not the diet that has failed, but those who have not understood that there is no way out of these troubles by retention: and that though it may be wise in early stages to go in for a little extra fruit and thus to moderate a too sudden rush of collemia, which might produce severe debility and anemia if unrestrained, this is only a temporary expedient adopted in the case of the debilitated and uric-acid clogged, because they are in these unfortunate conditions and require immediate help. Such help may have to be given either by fruit, bracing climate, cold water, or tonic drugs, and in all cases the result is to produce some retention; but we are often forced to do something of this kind unless we wish to see the patient sink into somewhat serious conditions of collemia, anemia, and debility.

Such treatment is, however, no necessary part of the uric-acid-free diet; it is to be regarded rather as a preliminary course to prepare the patient for it, and it is obvious that it is contrary to the ideal diet. The attempt to attain the ideal diet may have to be put off for a time in severe cases, but people are expecting the impossible if they think that a diet which permanently transgresses these rules will ever effect a complete cure either of gout or rheumatism (retention) or of collemia from the correlated plus excretion.

Some believe that the secret of long life is to be found in milk allowed to go sour or in the lactic acid thus produced, or again in milk which has been soured by some special process. But it follows from our first principles above stated that such acid foods may suit those who live in a fairly warm climate and who get their living by bodily labor, but it will not suit sedentary people, especially those who live in a cold climate such as that of England. Such acid food taken here will soon lead to retention, and so eventually to some loss of uric-acid-freedom.

I do not believe that the secret of long life is to be found in milk or in cheese or in bread or in nuts or in fruit, but in always living as nearly as may be on the natural diet of man, and in getting that food from the cereals, nuts, and fruit growing in, and therefore suited to, the country and climate in which one lives, together with more or less milk and cheese also produced on the spot.

The secret of long life has always had its foundation in obedience to nature, and man to be happy must use natural food obtained by his own labor. To force others to labor for you is to lose a great part of the reward.

In illustration of some of these points I will now mention some cases in which mistakes were made and their results. These were in people who had not understood the diet ideal, had not comprehended that all retention is wrong, and means, if not arthritis, at least collemia. The arthritis may be immediate, but the collemia may not appear for quite a long time, and in this case the retention is perhaps continued for many months and the patient imagines that all is going well, that the headache is cured, that the diet is doing no end of good.

Unfortunately a little later the picture is reversed, the relief has been due to retention not, as it should be, to reduced intake and free outflow and elimination of urates. This correct freedom will last for life; not so the freedom due to retention, for retention must come to an end some day, and then the headaches return and are for a time perhaps as bad as ever. But if the diet is continued, if the errors are put right, if the accumulations are cleared out, if the ideal is followed and no further retention is permitted, the real true freedom with tissues clear of urate and daily excretion equal to daily formation will yet be obtained and all will be well. Yet very many are unfortunately discouraged and give up the diet in disgust because they do not understand the cause of this failure. This is an unfortunate error for the patient, as it prevents his being relieved or cured; unfortunate also for the diet, as it fails to get the credit which is due to it.

M. F., aged 27, suffering from migraine. Has been on diet eighteen months; was much better at first, but the last three or four months (spring of 1908) has been nearly as bad as ever again. Inquiry brought out the following facts: All through last winter she had been eating fruit (oranges and bananas) fairly regularly, she has also not infrequently taken stewed prunes as a remedy for constipation. Now dried plums are perhaps as acid as any fruit in the world, and the sugar they contain is but an additional acid. I note that many of the public seem to think that a fruit which is sweet cannot be acid, as if the two things were contradictory, which of course is not the case. Fruit may contain a large quantity of acid even though it tastes sweet, and sugar when swallowed produces acids in the body, so that when fruit is bad fruit plus sugar or jam is worse. M. F. had also been taking rhubarb (a poisonous and highly acid vegetable) fairly frequently during the spring. Thus no doubt she has been retaining more or less all winter, and in the early spring when the uric acid thus provided was got into solution and passed into her blood with the return of the warmer season her migraine was for a time nearly as bad as ever, and the poor uric-acid-free diet got a bad name

Now what ought this patient to have done? It is easy to see the mistake she made, she broke the rules by eating fruit out of season in a cold climate, but what should she have done for the relief of her constipation? If she was in the position of the ideal laboring man, and had a hearty appetite, the constipation difficulty would be easily got over by eating freely of vegetables and salads with olive oil as is done in France. But this patient is sedentary and delicate, a town dweller with a poor appetite; if she is to eat much vegetable and salad she will not have room for her foods. She must at least not break the rules by taking fruit out of season in a cold climate, and if she can take potato freely and a little olive oil with that and some of her other foods (*e.g.* rice) she will not be much troubled with constipation.

Another case, G. M., a young man who has been on diet for some years and is completely cured of the migraine for which he began it. He nevertheless has occasional collemia, producing some depression and drowsiness, and is not as free as he should be from occasional colds or attacks of influenza. Now investigations shows that this is the result of his having got the idea that it is a good thing to be strong and braced up, as it is called, by exposure to cold. A practice copied from the meat-eaters, who of course require tonics of all kinds (drugs and climatic) to keep them well and fit for work.

Hence he has been careless of exposure to cold and has refused to clothe himself sufficiently or to put on a coat when other people would do so, his rooms have been kept too cold in winter, and in summer he has spent much time in bathing, of

which he is very fond, and has often done this on days regarded by others as too cold for bathing. Hence he has got more or less retention of uric acid in spite of a correct diet, and, when next exposed to heat or when the weather gets warm in spring, he has a corresponding amount of collemia with the results above mentioned. This of course has nothing to do with diet, yet those who do not understand the whole matter might say that here also the diet had failed. I have narrated some cases ("Uric Acid," edition VII) where still worse results were produced by exposure to cold.

If there is no retention by acids or cold, there will be no arthritis, colds, or bronchitis on the one hand, and no collemia, depression, or headache on the other; and a little constipation must be put up with or remedied by other means, for to attempt to get rid of it by fruit out of season is to sacrifice the greater to the less, and to lose that complete uric-acid freedom which it is the object of the dietetic and all other rules to obtain.

It is true that constipation, other things being equal, tends to raise acidity and cause retention, but this rise of acidity can be counteracted by increasing the quantity of potato. No doubt also it is always a misfortune to have acquired the constipation habit when living on flesh, and this is one more reason for beginning the diet in childhood. Another is that the habit of taking the more bulky foods is then easily acquired.

In the same way joint troubles may be better for a time if the patient begins the diet in summer and takes plenty of vegetables and only a little fruit, but they will come back again in the autumn and winter, if he takes fruit which is then out of season, if he exposes himself to cold or takes other liberties, having perhaps got hold of the erroneous notion that diet will protect him from all other causes of retention and trouble.

The same applies to skin diseases; if the diet is undertaken for any of these, they may be better at first and then relapse if any of the above-named mistakes are made. No doubt the uric-acid-free diet lessens the tendency, other things being equal, to all troubles that are due to its excess. It does not, however, remove all possibility of such troubles, for there is still some uric acid to be dealt with, and if through ignorance or carelessness this is allowed to accumulate, the old troubles will be reproduced to a greater or a less extent. But nothing of this kind need ever take place if the simple first principles of uric acid solubility are correctly understood, and if reasonable care is exercised.

Again we have a child who is ill as the result of exposure to cold and in spite of the uric-acid-free diet. Here it is not the patient who is to blame, but the parent of the patient. On inquiry we find that this child of three or four years old has been living all winter in a poorly warmed house, in a cold and damp climate, and has been allowed to go about the passages in a temperature but little above the freezing point, not only deficiently clothed but with absolutely no clothing on the greater part of the surface of its limbs.

If you make any remark on the bare blue limbs and the ice-cold hands and feet of such a child, the mother may quite probably urge in excuse that the little arms and legs "look so sweet," which is probably true, but unfortunately exposure of bare limbs to a temperature of 35° or 40° or even one of 45° or 50°, means retention of uric acid, and retention provides a store; and it matters not how the store is provided; once the store is there all, even the most deadly, effects of uric acid may result at some future time. Open windows at night are by many regarded as a cause of adenoids. Fresh air is good, but cold is not and may cause retention and rheumatic troubles in the child exposed to it.

Perhaps you are asked why such a child on a correct diet has colds? Why it has pharyngitis and enlarged tonsils? Why it has chronic nasal catarrh and adenoids? And why the surgeon has to be called in to deal with the tonsils or the adenoids? Or it may have laryngitis and be dangerously ill, or tracheitis or bronchitis; or a doctor, who is called in, may treat the bronchitis with amonium compounds (see "Uric Acid" Ed. VII or *British Medical Journal*, May 9, 1908), and then the unfortunate child may develop acute arthritis, and endocarditis or pericarditis, and all the other lesions of complete rheumatic fever.

You are asked to explain all this; the explanation has been given a dozen times over in every edition of my work above mentioned. Yet the inference of the patient is that the uric-acid-free diet is a failure, because it will not do what is impossible, because the presence of some little sense in diet will not make up for complete absence of common sense in other directions.

I will conclude by remarking that the solubility of uric acid and its excretion, and the things that control it cover a very much wider field than the mere answer to the question: What shall we eat or what shall we drink? It covers also the climate and the situation of our house, the way in which it is warmed and ventilated, the water we drink, the temperature of the water we wash in, the clothing we wear by night and by day, and the bodily exercise we get and the way we get it.

It may be difficult to bear all these points constantly in mind, but those who remember the above-mentioned ideal will make fewer mistakes. Its essential points are:—correct food, sufficient warmth, and the health-giving and appetite-producing effects of constant bodily labor in the open air. Play, athletics, or unproductive labor is never so good; it produces neither the all-round strength, the good constitution, nor the hearty appetite of the real thing, and is nearly always deficient in quantity and irregular in time.

7 Brook Street, Hanover Square.

PNEUMONIA ON THE ISTHMUS OF PANAMA.*

By W. E. DEEKS, M.A., M.D.,

CHIEF OF MEDICAL CLINIC, ANCON HOSPITAL, ISTHMUS OF PANAMA.

In this paper an attempt is made to outline the symptoms, complications, and treatment of 574 cases of pneumonia, occurring during the epidemic which began in the autumn of 1905, and which gradually subsided toward the end of 1907. These cases represent the greater part of those admitted to Ancon Hospital between the dates January 31, 1906, and October 25, 1907. About sixty cases occurred previous to the former date, but are not included in the series; neither are those which were admitted during the above-mentioned period but died within thirty-six hours after admission. Most of this latter group were moribund, and satisfactory histories could not be obtained.

Most of the cases were among the colored people,

* Read at a meeting of the Medical Society of the Isthmus Canal Zone.

natives of the West Indian Islands, and the mortality was 37 per cent. It is interesting to note the average mortality of the natives of the different islands.

Among the Barbadians there were 221 cases, with a mortality of 36 per cent.; among the Jamaicans, 71 cases with a mortality of 40 per cent.; Martiniquans, 69 case, 42 per cent.; Guadaloupians, 50 cases, 22 per cent.; Antiguans, 29 cases, 34 per cent.; Columbians, 19 cases, 52 per cent.; Granadians, 18 cases, 33 1-3 per cent.; St. Lucians, 15 cases, 33 1-3 per cent.; Panamanians, 12 cases, 58 per cent.; Whites, 20 cases, 20 per cent.

A striking feature is the severe mortality among the native Panamnians and Columbians (58 and 52 per cent.), who belong largely to a mixture of races. It was found in general that the mixed races showed poor resisting power in pneumonia.

I have been unable to ascertain why the natives of Gaudaloupe withstood the disease better than the rest of the West India Islanders, unless they were later importations, when food conditions were better. The number of cases which occurred among natives of the other islands was too small to draw any conclusions. It is seen, however, that the whites, which included those from all countries, suffered much less from the disease, and that the mortality (only 20 per cent.) was much lower than among the colored patients.

It was found that age played some rôle in the prognosis. Under thirty years of age there were 377 cases, with a mortality of 33.2 per cent. Between 30 and 40 years, 112 cases with a mortality of 37.6 per cent., and above 40 the death rate was 50.4 per cent. Those between 25 and 35 years of age withstood the disease best.

It was further found that 62 per cent. of the cases had been on the Isthmus less than six months.

In regard to etiological factors of the epidemic, a pneumonia board was appointed to investigate them. Dr. H. R. Carter was chairman, and the writer one of the members. The investigation was made along the following lines:

(*a*) The localities and buildings were investigated where pneumonia was prevalent, special attention being given to altitude, seasonal variation, environment, clothing, exposure to wet and draft, overcrowding, ventilation, prevalence of malaria, and house infection.

(*b*) The examination of clinical and pathological records to ascertain if acclimation or any other factors were concerned.

Under the first group of conditions the evidence was practically all negative.

Under the second group it was found from the histories that malaria may prove a predisposing factor, as histories of continued fever for several days preceding the onset of the pneumonia were common.

Most important, however, were Dr. Darling's pathological findings, as follows: (1) Among the autopsies of colored patients dead from other than pneumococcus infection 17 per cent. had a purulent sinusitis, a condition which in the United States would be usually considered as a result of a recent influenza. (2) That among autopsies of patients dead because of pneumococci infection the proportion of such sinusitis involvement was much greater, viz., 61 per cent. That was therefore good evidence of a connection between the purulent sinusitis and the pneumococcus in other organs acting directly as a cause, or both were the results of a common cause.

Dr. Darling stated in July, 1906, that the age of the sinus infection is appreciably greater than that of the lung or meningeal lesion, and concluded his observations with the statement that "the portal of entry of the pneumococcus is in most instances an inflamed accessory nasal sinus, the mucous membrane of which is fitted for the reception of the pneumococcus by an antecedent influenza or rhinitis."

It may be here noted that influenzal conditions were very common among the people on the Isthmus during the pneumonia epidemic, particularly among the new arrivals.

A similar observation to that of Dr. Darling's had been made in 1902 by T. S. Kirkland, of Sydney, N. S. W., during an epidemic there.

The symptoms chiefly complained of on admission were fever, headache, cough, pain, chill, vomiting, dyspnea, dysphagia, and dysentery. Herpes labialis, hiccough, delirium, icterus, and rusty sputum were very commonly observed.

Though on admission pneumonia was often suspected, positive physical signs could not be made out for two or three days after the onset. There seemed to be a focus of infection from which consolidation slowly extended throughout one or more lobes.

The severity of the onset is not a positive indication of the severity of its course or the development of complications.

It was not uncommon to have a patient admitted with a high temperature during the day and to find next morning a normal temperature, followed by a rise the next day to the maximum of the fever which continued throughout the course of the disease. It was also common to find a decidedly remittent malarial looking temperature for several days of the disease, particularly so in the milder cases. Neither rusty sputum nor icterus was any indication as to the lobe or lobes involved.

Deep jaundice was a sign of considerable gravity, as was also hiccough, though several recoveries occurred when these symptoms were present to a marked degree.

The lobes involved were as follows: right lower, 155 times; left lower, 136 times; right upper, 69 times; both bases, 39 times; the whole of one and part of the other, 31 times; right middle and lower, 27 times; complete right, 27 times; middle and upper, 20 times; right upper and lower, 19 times; left, complete, 18 times; left upper, 12 times; right middle, 11 times; right upper and left lower, 7 times; right middle and left lower, once, and both upper lobes, once.

The toxicity of the disease did not depend on the extent of involvement, but upon the virulence of the organism or the lowered resistance of the patient.

The leucocytes are an important factor in diagnosis, but vary within wide limits not only in different cases, but also in the same case.

A low leucocyte count (between 3,000 and 10,000) indicates either a slight attack and a favorable prognosis, or a very grave attack signifying lowered resistance in the patient, or great virulence of the infection, and is thus a symptom of great gravity. In fatal cases one count as low as 3,000 was recorded. In another two counts of 6,000 and 5,200 on successive days. In a third fatal case four counts were made of 8,000, 6,000, 13,400, and 9,600. In 40 fatal cases out of 100 in which a leucocyte count was made the leucocytosis was found to be 15,000 or under, that is 40 per cent.

In 55 cases out of 207 which recovered only 26.6 per cent. had leucocytosis of 15,000 and under. In

one fatal case with a leucocytosis of 7,600 there was found at death, acute hemorrhagic serofibrinous pleuritis, acute splenic tumor, subcutaneous and subendocardial ecchymoses, and intense parenchymatous degeneration of all the viscera. In another, with a leucocyte count of 14,700, the pathological report recorded fibrinopurulent pleuritis and pericarditis with pleuropulmonary tuberculosis. In another, with a leucocytosis of 12,200, there was found fibrinopurulent pleuritis and acute splenic tumor. In another, with 12,000, fibrinopurulent pleuritis, pericarditis, peritonitis, and mediastinitis. In another of 10,000, chronic nephritis, empyema, hemorrhage into the pericardium, and atrophic cirrhosis of the liver. In another of 12,000, empyema and fibrinopurulent pericarditis. In one of 13,600, empyema, which proved fatal. In one of 15,000, empyema, acute pericarditis, acute peritonitis, and chronic interstitial nephritis. In one of 15,000, empyema and mediastitis (fibrinopurulent). In one of 10,000, fibrinopurulent pleuritis, pericarditis, mediastitis, and acute nephritis. In another fatal case in which two counts of 5,200 and 6,000 were recorded there was found acute serofibrinous pleurisy, marked arteriosclerosis, chronic interstitial splenitis, and acute nephritis, and this in a patient of 29 years of age. In a Jamaican 26 years of age, admitted at midday with chills, fever, vomiting, herpes labialis, and hiccough, complete consolidation of the right lung was found, with a leucocyte count of only 7,600; on the fourth day the same; on the sixth, 8,200, and on the ninth, 11,600. At autopsy pneumococcal cerebrospinal meningitis was found as a complication. In a boy aged 20, with right upper lobe involvement, four leucocyte counts during the course of his illness gave 8,000, 6,000, 13,400, and 9,600, respectively, and at autopsy fibrinous pericarditis and purulent sinusitis were found. In another patient, 29 years of age, with right upper lobe involvement and a leucocytosis of 8,600, chronic nephritis was the only complication. In a man, 37 years of age, with left apex involvement and a leucocytosis of 8,400 (empyema and acute nephritis complicating the condition) a good recovery was made. In another, aged 30, who had complete left lung and right lower involvement the leucocyte counts gave 6,600, 4,000, and 13,600. He also made a good recovery from an empyema which followed. In another, in a man aged 30, with right lower involvement and a leucocytosis of 7,000, which proved fatal, empyema, purulent sinusitis, and chronic interstitial nephritis were found at autopsy.

Contrary to all this, I found recorded in a boy aged 20, who had the whole right and left lower involved, a leucocytosis of 70,000. He developed an empyema and plastic pericarditis, but made a good recovery.

The above cases are sufficient to illustrate what was above mentioned, that a low degree of leucocytosis in pneumonia is on the one hand a condition of gravity, showing lowered resistance on the part of the patient, while, on the other hand, patients with a low leucocytosis made a good recovery. It was generally found that either there was slight involvement of one lobe or an incomplete lobar pneumonia, and very frequently the development of an empyema followed without other complications. In these cases there was probably an attenuated virulence of the infective agent.

Leucocytosis therefore may be said to be a valuable prognostic sign, but only in conjunction with the other symptoms and physical signs present.

In three cases complicated with typhoid fever, all of which proved fatal, the leucocytosis was 23,800, 22,000, and 15,000, respectively.

In the series of 574 cases the following complications occurred: Acute nephritis in 54 cases, chronic interstitial nephritis in 40 cases; acute pericarditis, either fibrinous, hemorrhagic, purulent, or suppurative, in 40 cases; empyema in 45, with 19 recoveries (when uncomplicated these cases usually recovered); malaria in 16 cases; acute ulcerative colitis in 10 cases; meningitis in 6 cases; abscess of the lung in 3 cases; parotitis in 3 cases; endocarditis in 2 cases; arthritis in 2 cases; otitis media in 1 case; amebic dysentery in 7 cases; thrombosis of the abdominal aorta in 1 case; peritonitis in 7 cases; pancreatitis in 3 cases; mediastinitis in 6 cases; uncinariasis in 121 cases; myocarditis in 4 cases; empyema of the gall-bladder in 1 case; cerebral hemorrhage in 3 cases; gangrene of the lung in 1 case; atrophic cirrhosis of liver in 3 cases.

Practically all those died who had chronic interstitial nephritis or atrophic cirrhosis of the liver, and most of the patients who developed acute nephritis.

As will be seen from the above, uncinariasis was present in 121, or about 20 per cent., of the cases. It was only when the uncinariasis gave rise to severe anemia that this affection added to the gravity of the prognosis.

The most striking factor in the above analysis, however, is the small number of cases complicated by malaria; only sixteen being cases recorded in which the organism was present.

This observation has been repeatedly verified since, and it may be said in general terms that malarial organisms and leucocytosis are incompatible conditions in the human organism. Leucocytosis takes care of malaria, and in the treatment of pneumonia even the presence of the organisms need not be considered in the general management of the case.

On the other hand, it may be noted here that leucopenia, which is present in typhoid fever, is not incompatible with malaria, and here these two affections are found almost constantly to coexist, and necessitate the administration of quinine through the whole or a great part of the course of the former.

Another striking complication is amebic dysentery, which developed in seven cases during the progress of the affection. At the onset there was no dysentery. Two cases in which this complication was present terminated fatally. Another unusual complication encountered was thrombosis of the abdominal aorta.

In regard to the treatment of the pneumonia patients some important facts have been noticed. It is not the object of the writer of this paper to discuss the smaller though important methods of treatment, such as rest, fresh air, and general hygiene, but to point out particularly the misuse of an important drug which modern medicine not only sanctions, but teaches to be of special value in the treatment of pneumonia. The reference is to quinine. In a district where malarial infection is almost universal it is but natural to assume that quinine here would be a *sine qua non* in the therapeutic armament for the management of pneumonia patients. The direct opposite has been found to be the case. As mentioned above, only in 16 bloods of the 574 cases examined were the malarial plasmodia found on the day of admission to the hospital, and since special attention has been directed to this point the general principle may be formulated that leucocytosis destroys or is antagonistic to the pathological

activity of the malarial parasite. When this was noted the use of quinine in the treatment of pneumonia cases was discontinued, and it was used only on the day of admission, before the diagnosis was made. On analyzing the results the following percentage of comparative mortalities was obtained: Total mortality in the 574 cases, 37 per cent.; mortality of 338 cases treated with quinine, 41.4 per cent.; mortality of 236 cases treated without quinine, 30.5 per cent.—a clear gain of almost 11 per cent.

It is also interesting to note that in 164 recoveries from pneumonia in which no quinine was used, though the convalescence was frequently tedious, no malaria developed while the patients were in the wards. Leucocytosis would be looked upon in pneumonia as a conservative process; in other words, it would be regarded as Nature's method of fighting the disease.

From this viewpoint permit me to quote a few extracts from H. C. Wood's "Therapeutics, Its Principles and Practice," on the physiological action of quinine. He says:

"We think it more than probable that after *a few doses the alkaloid is practically eliminated in forty-eight hours,* but that when it has been given continuously, or when kidney disease or great feebleness of circulation exists, the system may contain a notable amount of the quinine for a longer period."

"Two facts, first pointed out by T. A. Chaperon, have been so abundantly substantiated that we must accept them as established. They are, that in *small* doses quinine causes in the frog a lessening of the reflex activity, which is removed by section of the medulla, and in *large* doses it produces a permanent palsy of reflex activity."

"In man, very large doses of quinine (thirty to sixty grains) lower the force and frequency of the pulse; a pulse-rate of 40 has been noted, and in reported cases of quinine poisoning the pulse has been imperceptible at the wrist. Under the latter circumstances the pulse-rate may be increased, but the cardiac force is reduced to a minimum. The evidence is conclusive that both in man and in the lower animals *quinine in sufficient amount is powerfully depressant to the heart muscle or ganglia.*"

"It is probable, therefore, that the *fall of the arterial pressure in poisoning by quinine is in part the result of an action upon the vessels.*"

"In 1867 Binz announced the fact that quinine added to human blood in the proportion of 1 part to 4,000 immediately checks and in a short time arrests the ameboid movements of the white blood cells. Confirmation of this has been furnished by Scharrenbroich, by Kerner, by Geltowsky, and by Jerusalimsky. The minimum effective strength of the solution has been found to vary in different species of animals, and even in different individuals of the same species."

"The correctness of the original observation of Binz, that quinine checks the outwandering of the white blood corpuscles in the irritated mesentery of the Cohnheim frog, must be considered as established, but it is not proved that the failure of the blood corpuscles to escape from the irritated vessels is due to the arrest of their ameboid movements by the quinine."

"The investigations of Binz appear to show that the alkaloid lessens the ozonizing power of the blood; for he found that in young cats to which he had given a very large but not fatal dose of quinine the freshly drawn blood affected the tincture of guaiac much less than it normally should."

"As it is established that quinine exerts some antipyretic action in ordinary fever, it is a plausible theory that the lowering of temperature is due to a checking of the ozonizing power of the blood."

"Considering all the evidence, and especially the rather recent very elaborate studies of Prior, we are wararnted in believing it established that *quinine powerfully depresses the elimination of the nitrogenous excretory principles.* That such decrease is due to diminished formation, and not to lessened elimination, seems proved by the fact that in Prior's experiments there was no increase of nitrogenous excretion beyond the normal following the omission of the quinine. It seems, therefore, to be established that quinine has *a direct or indirect depressing influence upon the tissue changes of the human organism.*"

We have, therefore, in the physiological action of quinine directly antagonistic principles to what is sought in the management of pneumonia cases. In brief, its action is cumulative, depressing to the nerve centers and the respiratory and circulating organs. It interferes with the development of leucocytosis by preventing the emigration of leucocytes from the blood, reduces the ozonizing powers of the erythrocytes, and interferes with the elimination of waste products.

It also acts as an antipyretic in reducing temperature, but this is scarcely to be desired when, according to Fraenkel, the discoverer of the pneumonia diplococcus, the organism rapidly loses its pathogenic properties by cultivation at 41° to 42° C. (105.8° to 107.6° F.).

From the above evidence it may be concluded that quinine in large doses in pneumonia is contraindicated.

The drugs at present made use of in the treatment of pneumonia may be said to be at the onset (if much pain be present) ¼ of a grain of morphine hypodermically; tincture of the muriate of iron in ½ dram doses three times daily. This is done because of the marked anemia which has hitherto characterized the patients here, due in great part to intestinal parasitism and poor food. Strychnine and nitroglycerin hypodermically; as much as 1-30 grain of the former and 1-100 grain of the latter may be given as frequently as every three or four hours, and whiskey *ad libitum.* It has been given when there was a great deal of toxemia up to 18 ounces in 24 hours. Much less (6 or 8 ounces daily) is generally given toward the end of the disease.

In mild cases no medication at all is necessary, but in severe cases the pulse must be frequently watched and the stimulants varied accordingly.

As a rule, nothing is necessary the first three or four days, then stimulation is begun as the symptoms or condition of the patient indicate. During the course of the affection an occasional dose of magnesium sulphate is considered good treatment, particularly if constipation be present. In extreme cases saline enemata are of great value, apparently often tiding the patient over a crisis. These may be given in quantities of six or eight ounces every three hours, particularly if the patient is not taking nourishment well. As a rule, they are retained. If the case is a very toxic one, a gallon or more of warm physiological saline solution is used to lavage the bowels.

In other words, the treatment practised here is supportive and eliminative, and in the class of patients that we have to treat, with their numerous complications, the results on the whole must be considered at least satisfactory.

EARLY TUBERCULOSIS AND MALARIA; THEIR DIFFERENTIATION.*

By PAUL H. RINGER, A.B., M.D.,

ASHEVILLE, N. C.

Cases of incipient pulmonary tuberculosis, particularly in individuals coming from malarial districts, are so often diagnosed as malaria, and proper hygiene and diet not resorted to, that a few words on the differentiation of these two diseases may not be amiss.

The differential diagnosis is at times difficult—usually, however, it is quite possible if the case be studied carefully. Let it be understood at the start that reference is not made to pernicious malaria—to malarial cachexia—but to tertian, quartan, and estivo-autumnal malaria, as opposed to first-stage pulmonary tuberculosis.

The diagnosis may be considered under three distinct headings: (1) Clinical Symptoms, (2) Laboratory Findings, and (3) Therapeutic Test.

Clinical Symptoms.—Chills. In both diseases we may have actual chills or chilly sensations, but a definite rigor speaks far more in favor of malaria than of tuberculosis, cases of the latter disease having marked chills being usually so far advanced that a correct diagnosis forces itself.

Fever.—A common symptom of both diseases, usually higher in malaria than in early tuberculosis, and rising suddenly in malaria as compared with a gradual ascent in tuberculosis. The fever of malaria comes on with a rush—the patient is seized with a chill, and in twenty minutes has a temperature of from 101° to 104°. A very typical temperature curve of incipient pulmonary tuberculosis, taken from the record-book of one of my patients, is the following: 11 A. M., 98.8°; 1 P. M., 99.5°; 3 P. M., 100°; 5 P. M., 100.6°; 7 P. M., 99.8°. A carefully kept two-hourly temperature record is one of the best means of differentiating the two diseases.

In malaria the fever usually drops by crisis; in tuberculosis by lysis. However, in the estivo-autumnal type of malaria, fever may last more than twenty hours (this not occurring in early tuberculosis) and fall by lysis—the fever in this type of malaria may even be continuous, the picture then being suggestive of typhoid fever rather than tuberculosis.

Sweating.—Far more profuse in malaria than in early tuberculosis, where real sweats are uncommon. Drenching sweats occur only in the more advanced cases of tuberculosis; in malaria they may occur after every paroxysm of fever.

General Feelings.—A most important point in my opinion is the fact that between paroxysms the malarial patient feels well—the tuberculous patient feels sick. The malarial patient (unless he be the victim of an old chronic malarial poisoning) recovers swiftly from his paroxysm. The tuberculous individual, if running a temperature, is constantly a prey to the tuberculotoxins, and consequently feels weak and below par all the time.

Bronchitis.—May be a symptom in both diseases—in malaria is usually diffuse and at the bases of the lungs posteriorly—in early tuberculosis often sharply localized and at an apex.

Breath Sounds.—These are of paramount importance, particularly in the apical region. Rough breathing has been well pointed out by Grancher to be the first detectable physical sign of pulmonary tuberculosis. With an afternoon fever, whether preceded by a feeling of chilliness and followed by a sweat or not, if at one apex the breathing is roughened as compared with that of the opposite apex, whether expiration be prolonged or not, a diagnosis of incipient pulmonary tuberculosis is so probable as to be justifiable. Dullness and râles need not be awaited; they occur when the tubercles have coolesced and when bronchitis has set in. Rough breathing denotes discrete tubercles. Careful auscultation above the clavicles, and particularly in the first intercostal space close to the sternum, is a *sine qua non* for the earliest possible diagnosis of pulmonary tuberculosis.

Splenic Enlargement.—Usually present at some time in malaria—not found in tuberculosis.

Herpes labialis is not seen in early tuberculosis. According to Osler, it is almost as frequent in malaria as in acute lobar pneumonia.

Laboratory Findings.—The blood and sputum should be carefully and (if negative) repeatedly examined in making this differential diagnosis. I again say repeatedly, for one negative examination, whether for malarial plasmodia or tubercle bacilli, is worth nothing. Furthermore, the plasmodia are often found, but at certain times, preferably during the height of the fever. Not long since, in the private laboratory of Dr. Charles L. Minor, of Asheville, I examined the blood of a patient taken while having a chill in the office. No plasmodia were demonstrable. Half an hour later, the patient being in the febrile stage, more blood was examined, and in almost every field of the microscope two or more plasmodia were found. The stain I prefer is the ordinary Jenner, on account of its rapidity and simplicity. When possible, the fresh, unstained blood should be examined as well as stained specimens. In examining for tubercle bacilli, morning sputum should be chosen and the thickest bits selected. Much of the success in finding tubercle bacilli depends upon perfect technique, which cannot be entered into here, but with proper smearing and staining methods they should be demonstrable if present at all.

We can assert that, if blood and sputum be carefully and repeatedly examined for plasmodia and bacilli, if all examinations be negative, if there be ever so slight a change in the breath sounds at one apex, if intermittent fever and general malaise persist, the case is one of tuberculosis and not of malaria.

Therapeutic Test.—Osler has given us an axiom, "An intermittent fever that resists quinine is not malarial." Therefore, if needs be, let quinine be exhibited; if the patient recovers, malaria was present; if not, malaria can be excluded.

Stress should be laid upon the fact, particularly in malarial districts, that tuberculosis may set in with fever typically intermittent in character, and daily chill with subsequent fever and sweat; but careful note of the points mentioned should clear up the etiology of the febrile movement.

The importance of a correct diagnosis between these two conditions is more than apparent. Yearly scores of people are sent to Asheville from all parts of the country to rid their systems of malaria, when in point of fact the tubercle bacillus is the prime factor. We do not deny that the two diseases can and do coexist; but we do urge that the most important diagnosis is that of tuberculosis. In this country malaria seldom kills. Tuberculosis is our greatest scourge. Quinine in proper doses will shortly arrest malaria; months of rest, fresh air, good food, and a minutely regu-

*Read at the meeting of the North Carolina Medical Society, Winston, N. C., June 16, 1908.

lated life are essentials to the cure of tuberculosis. Malaria is not communicable save through an intermediate host. Every careless or ignorant tuberculous patient expectorating broadcast is a serious and dangerous menace to his family and to his community. Let us, therefore, take these facts to heart, and, even though residing in a malarial district, when a patient presents himself with symptoms suggesting paludism, let us well consider the pros and cons, and exhaust all our scientific knowledge in an earnest effort to discover positively whether we have to deal with the *Plasmodium malariæ*, or with the bacillus of tuberculosis.

33 Haywood Street.

ACUTE OTITIS INTERNA, WITH REPORT OF A CASE.

By EDGAR R. STILLMAN, M.D.,

troy, n. y.

The following account of a case of panotitis, Politzer, or acute primary otitis interna, Voltolini, is of interest because of its rarity. In fact, primary disease of the internal ear is so uncommon that many authors deny its occurrence. Ziegler, in his "Lehrbuch der Pathologischen Anatomie," says: "Primary nontraumatic inflammation of the labyrinth has not yet been proven." And yet, if inference is of any value at all in medicine, no other conclusion can be reached than that these cases are due to an acute inflammation of the labyrinth. The literature of the condition seems to be very scanty. In the past twenty-five years, in particular, the references to the condition are very few and incomplete. I have not been able to find a case reported with autopsy, for the reason that the patients always recover, and only accidentally would such an opportunity be afforded. But enough has been done in the post-mortem examination of adults deaf from childhood to establish firmly the fact that in childhood some acute inflammation of the labyrinth had taken place. Politzer states that the occurrence of a primary inflammation of the labyrinth has been established beyond the possibility of a doubt both by clinical observation and by several post-mortem examinations.

The disease is an interesting one historically, since, although described many years ago, its identity as a separate condition has not yet been established. The first account seems to have been written by Kramer in his "Die Erkentniss und Heilung der Ohrenkrankheiten," Berlin, 1849, which, however, seemed to have aroused no particular interest. In 1861 Ménière of Paris again described it and taught that it was due to an acute labyrinthitis. Voltolini, however, was the first to emphasize the importance of the condition, and in a series of communications and reports of cases to focus the attention of the profession upon it. His first communication was published in the *Monatschrift fur Ohrenheilkunde*, No. 1, 1867, in which he asserted that it was a specific disease of childhood, coming on suddenly with vomiting, headache, fever, sometimes with convulsions; the disease lasting three to eight days, with a resulting absolute deafness. This account was the first to receive much notice from the profession, and from this fact the disease has been known as otitis labyrinthica Voltolini. In the next ten years considerable discussion arose concerning the condition. Voltolini, on the one hand, contended for an acute primary labyrinthine disease, while, on the other hand, von Troltsch, Politzer, Moos, and others contended that the disease was an abortive form of epidemic cerebrospinal meningitis. Voltolini, in 1882, published a very interesting monograph, in which he thoroughly discussed the two conditions and answered in particular the objections of his critics who differed from him in regard to the possibility of an acute primary otitis interna.

Voltolini reported fifty-one cases in his monograph and mentions having seen many more. He sums up the symptomatology of the condition in the following words, which express very vividly the clinical picture: "An acute inflammation of the membranous labyrinth usually mistaken for meningitis was first described by me in *Monatschrift fur Ohrenheilkunde*, No. 1, 1867. It occurs almost without exception in children. A perfectly well child is seized suddenly with vomiting, headache, occasionally with earache, high fever and sometimes with a convulsion. They are usually conscious and urine is voided and bowels are moved in a normal manner. The force of the disease seems to have expended itself in from three to eight days, and the physician congratulates himself that the case of meningitis has gotten well so quickly. But soon it is discovered—it may be within twenty-four hours of the disease—that the child is completely deaf. It gets well quickly with the exception of a staggering gait, plays about again after a few days, his appetite returns, but he remains completely deaf and soon forgets how to speak; he has become deaf and dumb." The keynote to the diagnosis then is the early and complete deafness, with rapid recovery in a child whose symptoms indicated some acute intracranial inflammation.

In contrast to this description of Voltolini, Politzer in his "Diseases of the Ear," reports a series of cases of panotitis, in which the same clinical picture was presented, but in which the inflammation was of a more severe grade and went on to suppuration and extension of the process into the middle ear and neighboring tissues. In the case observed by the author this also took place, as shown by the late bursting of the drum and discharge of pus.

The cases of Politzer are as follows:

"In a child three years old the affection began with fever, followed in the course of several hours by an eclamptic seizure without loss of consciousness. Sudden deafness developed after thirty-six hours. On the tenth day after the fever remitted, a discharge from both ears began, which ceased after fourteen days. Four days later an abscess formed behind the right ear, which was opened and healed after a short time. The hearing for every kind of tone and noise was completely lost.

"In a boy three years old high fever and headache without loss of consciousness occurred three weeks after the first examination. After two days a slight discharge was noticed from both ears, with an abatement of the fever. The parents noticed at the same time that the patient had become totally deaf and that it staggered so markedly in walking that it fell after taking a few steys. The objective examination showed perforation of both tympanic membranes and total deafness without the least trace of perception for sound.

"A girl three years of age was suddenly taken with high fever during the night of April 15, 1879.

Toward morning unconsciousness set in with slight eclamptic seizures and contractions of the muscles of the neck, which lasted fourteen days. After the return of consciousness total deafness and a staggering gait were observed. In the eleventh week a discharge was observed from the left ear, which ceased in three weeks. Objective examination of the right showed a retracted reddened membrane of the left ear, a dry perforation in the anterior inferior quadrant. There was total deafness as in the two previous cases."

There can be no doubt, Politzer states, that in these cases "the middle ear and the labyrinth were affected. Whether, however, the process arose in both parts of the ear simultaneously, or whether it affected one sooner than the other could not be determined, as the cases were not observed from the beginning of the attack." "The late appearance of the discharge in the third case eleven weeks after the commencement of the affection would indicate that the suppuration might possibly have originated in the labyrinth and that it extended to the middle ear after perforating the round and oval windows." In the case observed by the writer there can be no doubt that this was the sequence of events, since careful examination of the ears was made very early. The total deafness was first and examination of the ear was negative so far as any indications of middle-ear trouble were concerned. Examination with the tuning fork showed an absolute obliteration of perception for sound, either by bone or aërial conduction.

It would seem, then, that these two diseases, panotitis and otitis labyrinthica of Voltolini, represent conditions that have many points in common and in many cases may represent identical conditions depending on the severity of the process. The bacteriology of the disease also might prove of service in studying its nature and mode of development. The case in question is the following:

J. S., 7 years old, schoolboy, German parentage, was first seen by me January 10, 1906. He had been sent home from school the day before because of headache, pain over the right eye, and feverishness. Family history negative; father and mother alive and well; six children alive and well; no miscarriages, and no history of any hereditary disease. Personal history also negative; child had measles with complicating pneumonia at two years, since which time he has always been well; entered school at six years and made satisfactory progress. There was no history of any previous ear disease.

At the first examination I found the child in bed complaining of headache. He had been delirious the night before and at the time of examination was very drowsy and evidently prostrated by some serious disease. Objective examination was negative; no photophobia, no Kernig's sign, no rigidity, nothing evident on abdominal examination, no evidence of any disturbance of the respiratory, circulatory, or gastrointestinal systems. Nothing to cause suspicion of any trouble with the ears. Child had vomited once, not projectile in character. Temperature 103°.

A dose of calomel with a fever mixture was prescribed. He passed a rather restless night and in the morning appeared prostrated and stupid; he could be aroused, but only by shaking and then would glance around in a strange sort of way and close his eyes again. He would not answer questions and seemed not to comprehend their meaning. I believe his peculiar behavior at this time was due to his complete deafness. His fever had subsided somewhat, his bowels had moved several times, and his general condition seemed a little better. He slept all the time except when roused for medicine or nourishment.

The next morning the conditions were unchanged, but it was discovered that the boy was totally deaf. An examination of the ears was negative; the tympanic membrane showed no redness or swelling; he complained of no pain or soreness about the ears and of no subjective noises. Examination with the tuning fork showed absolute loss of both aërial and bone conduction. No evidence of any other cranial nerve involvement. His head still ached slightly; he was still a little feverish, but his general condition seemed to be somewhat improved. He could recognize objects and could read as well as usual. He continued to improve and the next day found him playing about in bed with his toys, but with absolute deafness.

At the end of the week he was so much better that he was allowed to get up, when it was first noticed that he staggered on attempting to walk. His gait resembled the gait of cerebellar ataxia or that of a drunken man. Repeated examinations of his ears were made, but up to the time when he passed out of my observation nothing could be detected. From this time on improvement was steady and rapid. The staggering improved, and in a week or ten days the child was playing about and seemed well.

On February 4, twenty-five days after the onset of his deafness, both ears discharged without having given any previous pain or discomfort. At this time the patient had passed out of my control and observation, but was reported to be as well as ever, but totally deaf.

This case then represents typically the clinical picture associated with the disease as described by Voltolini and Politzer. The difficult question to be settled is the relation of these cases to meningitis. It remains for future studies to further elucidate this relationship or nonrelationship. Cases like that above described must, however, be rather infrequent, and the study of a series of cases is by reason of this fact made difficult. A complete study of a large number of cases of meningitis with ear complications would, however, prove of service in this relation. As stated before, Voltolini, out of a large number of cases, had never seen a death, so that no opportunity for autopsy on a recent case has been afforded.

The etiology of the disease is very obscure. It occurs exclusively in children, no cases of the disease having been reported in adults. Atmospheric conditions, dampness, etc., have been described as etiological factors, but without much reason. Its relationship to epidemics of cerebrospinal meningitis has not been clearly shown, and further observation on this point should furnish valuable information. Sex or season seems to have no influence. At the time my case occurred a mild epidemic of influenza was present and a possible relationship to this disease should be considered.

The diagnosis of the disease is easy after the characteristic symptom, total deafness, has developed, but is impossible before this. The symptoms are of such a general nature that it is unsafe to venture any positive opinion. They suggest meningeal irritation, but there is no objec-

tive evidence of this beyond the prostration, vomiting, fever, headache, and possibly convulsions. Examination of the ears is negative. The disease with which it is most likely to be confounded is meningitis, particularly sporadic cases of the epidemic type. The clinical points of difference are best illustrated by a study of the following table modified from Voltolini:

Meningitis.	*Labyrinthitis.*
Epidemic or sporadic.	Sporadic only.
Attacks adults and children.	Attacks children almost without exception.
Ears usually not both involved, and if so, not to same extent and showing tendency to improvement.	Both ears always symmetrically involved and total deafness.
Other cranial nerves may be affected.	Other cranial nerves never affected. Child otherwise well.
Convalescence prolonged and miserable.	Convalescence quick, with deafness.
Herpes labialis common.	Herpes very uncommon. Observed once only.
Convalescence marked by great weakness and prostration. Giddiness and dizziness not especially frequent or remarkable.	No especial weakness, but giddiness and dizziness constant and long continued.

The prognosis of the disease is invariably favorable. No deaths have been reported and no autopsy on a recent case has been made. The pathology of the condition is therefore obscure, and the necessity of the careful study of cases with modern laboratory methods is evident.

GONORRHEAL EXOSTOSES OF THE OS CALCIS; REPORT OF A CASE COMPLICATED BY METATARSALGIA.*

By ARTHUR J. DAVIDSON, M.D.,
PHILADELPHIA, PA.
INSTRUCTOR IN ORTHOPEDIC SURGERY, JEFFERSON MEDICAL COLLEGE.

Numerous are the conditions which come to notice of an orthopedic surgeon, which have for their chief symptom a painful heel. Among such can be mentioned certain forms of flatfoot, in which this symptom is induced by a stretching of the plantar fascia; also tuberculosis, neoplasms, osteomyelitis, neuritis, bursitis, rheumatic and inflammatory processes. An affection, less common than the above-mentioned and giving rise to the sympton, painful heel, is the subject of a case that I am taking the liberty to report, namely, gonorrheal exostoses of the os calcis.

It has been noted by Bradford that the os calcis gives attachment to important groups of muscles, viz., those ending in the tendo Achillis and the plantar muscles, with, in addition, the plantar fascia. Furthermore, that under certain conditions, not yet thoroughly understood, abnormal bone growths are developed at the insertion of important muscles which are subjected to strain.

*Read at a meeting of the J. Autken Meigs Medical Association.

It would, therefore, be expected that in a bone as important as the os calcis, and subjected as it is to injuries and strains, there should be abundant exostoses in these two regions. It will not be the object of this paper to discuss cases of traumatic origin. This subject has been very elaborately studied and presented by Bradford, in his recent article entitled "Exostoses in the Plantar Portion of the Os Calcis."

From Baer's cases and also those of Jaeger of New York, it would appear that in the blenorrhagic condition this tendency to the bone deposits is increased. Painter of Boston described a case of painful heel, in which he found multiple exostoses on the posterior portion of the os calcis, associated with an inflammatory process of the bursa behind the tendo Achillis. He thought that the lining membrane of this bursa was the starting point of these exostoses, and that they were osteoarthritic in nature. Nobl of Vienna described a similar condition. He regarded the seat of infection to be from the sheath of the tendo Achillis, and thought it to be gonorrheal in origin. Baer reports six cases, five of which give a clear history of gonorrhea. Jaeger reports eleven cases, describing but one of gonorrheal origin. It is interesting to note that both Baer and Jaeger describe a case similar to the one that came under my observation at the orthopedic out-patient department of Jefferson Medical College Hospital, presenting a clear history of gonorrhea, gonorrheal arthritis of the ankles, and resulting multiple exostoses of the os calcis.

The condition can be described as occurring only in males. Of the cases reported none have occurred in women. It occurs between the ages of eighteen and thirty, although one case has been reported in a man of thirty-four. Traumatism does not seem to be a factor in the production of this class of cases.

Some time following an attack of urethritis, usually from three to nine months, the patient complains of sharp, severe pains in one or both heels, usually coming on simultaneously in both heels. The pain can be sharply localized in the center of the plantar surface of the heel, and is elicited only by weight bearing or direct pressure. The pain may be so severe as to incapacitate the patient. The gait is characteristic. The weight is borne by the ball of the foot and the patient walks, as it were, on his toes. His steps are slow and careful.

The diagnosis depends first upon the history. A disease of adult life, occurring usually in males, and making its appearance some time following an attack of urethritis. Consider that it is a bilateral disease, the pain appearing simultaneously in both heels or in one closely following the other; again the character of the pain, the attitude and the characteristic gait. The os calcis will be found enlarged and thickened in most cases. A radiograph will confirm the diagnosis.

The only satisfactory treatment is operative.

The following is the report of a case:

A. L., male, age 26 years, complains chiefly of painful heels. The family history is negative. The patient has had diphtheria, measles, and malaria. About five years ago he had an attack of gonorrhea. During the third week of the disease he developed severe pains in both ankles. From the right ankle the pain shifted to the great toe and also up to the knee. The patient was admitted to the Rhode Island Hospital, there treated, and discharged at the end of one month, cured

of the urethritis, and with the joints in a normal condition. About one and a half years later he again had an attack of urethritis. The pains returned, this time attacking both ankles, also shifting across the left metatarsal arch. The pains continued for about two months, gradually becoming less severe. Following this illness, the patient constantly complained of a soreness in both heels when bearing weight on the feet. A year and a half later he had a third attack of gonorrhea. This time he developed pains in both ankles, but not so severe as on the previous occasions. The pains shifted from the ankles to the heels. He was left with a constant soreness of both heels on pressure or weight bearing. No pain when at rest.

On examination it was seen that the patient walked with a slow, careful, guarded gait, protecting the heels at every step. There was a localized spot of tenderness on pressure over the insertion of the tendo Achillis on the posterior surface of each os calcis, also a spot of marked tenderness on the center of the plantar surface of the heel. There was a painful area over the metatarsophalangeal articulation of the fourth toe of the left foot, the pain of which was greatly intensified upon pressure. There was apparent enlargement, with thickening of each os calcis.

The radiograph showed an exostosis at the tubercle of each os calcis, and another at the insertion of the tendo Achillis. There was a definite thickening about the sides of the bone.

An incision about one and one-half inches long was made on the inner side of the heel. The soft parts were dissected aside and the tubercle of the os calcis exposed. The exotosis was removed by means of a chisel. The same procedure was resorted to over the insertion of the tendo Achillis. On the left foot a vertical incision was made, one and one-half inches long, from the proximal interphalangeal joint and extending upward in the central line of the fourth toe. The extensor tendon was pushed to one side and the metatarsophalangeal joint exposed. The metatarsal bone was now divided as close to its head as possible by means of powerful sharp-pointed, narrow-bladed cutting pliers. The head of the bone was then separated from all remaining attachments and removed. The wounds were closed with silkworm gut sutures and cigarette drains were left for twenty-four hours. The wounds all healed by first intention. The stitches were removed at the end of a week. Weight bearing was started at the end of twelve days.

The condition of the patient two months after the operation is as follows: Gait normal, no pain in the plantar portion of the heel, no pain over the fourth metatarsophalangeal articulation of the left foot. There is still some soreness over the insertion of the tendo Achillis on pressure or following prolonged weight bearing. This is probably due to excessive callus formation, as it has been gradually disappearing since the operation.

Gonorrheal Exostoses of the Os Calcis, from a Radiogram by Dr. W. F. Manges.

The pathological report by Dr. Randle C. Rosbenberger was to the effect that the head of the metatarsal bone was slightly enlarged and markedly eburnated. Cultures in blood serum were taken from the exostoses, all of which proved to be sterile.

Uterine Endoscopy After Abortion and in the Normal and Pathological Puerperal State.—Ch. David brings forward a new instrument for the examination of the uterine lining after abortion or labor. Its use is easy, painless, has no inconveniences, and gives valuable information as to the contents of the uterus and the condition of the endometrium. It shows the existence of membranous or placental remains, the presence of septic endometritis or ulceration, allows of the diagnosis of instrumental perforation of the uterus in criminal operations, and aids in the diagnosis of such uterine deformities as double uterus. A fragment of placenta may be removed or an application to the uterine lining may be made through the instrument. It consists of a tube open at the fundal end, which contains another tube closed with a glass plate so as to prevent the obstruction of vision by blood oozing from the lining. In this inner tube is placed an electric light which gives clear vision of colors and other visible conditions that denote ulcerations, clots, or abnormal secretions.—*Bulletin de la Société d'Obstétrique de Paris.*

New York, October 3, 1908.

THE TUBERCULOSIS CONGRESS.

IT is said of a certain writer, whose idea of perspective was a little confused, that he made one of the characters of his historical romance begin a discourse with the words: "We men of the middle ages," etc. It is not often that one has such a realizing sense of where he is and what he is doing in the light of history, but one does not need it to see the significance of the present warfare against tuberculosis. There never was in the history of the world a movement such as this, one participated in by all the peoples of the earth, laymen and physicians of every nation of the civilized world, from both the Americas, all of Europe, India, China, and Japan, the islands of the Pacific, and the extremes of Africa, all united in a common cause—the suppression of a disease which threatens, if unchecked, to exterminate the human race.

The loss to the world from this disease has been immense; art, literature, science have all suffered in incalculable measure from its ravages, and the imagination fails to compass what might have been accomplished for the elevation of the race by those who have been cut off by it in the first years of productive manhood. But more serious even than this is the loss of the workers, those who produce, who add to the comfort, the happiness, and the wealth of mankind. The world can exist without its geniuses, but without those who make the necessities of life, the food, the clothing, and the habitations of man, it would be a waste. And it is among the workers that the havoc wrought by tuberculosis is greatest. As Dr. Pannwitz of Berlin said, at the Tuberculosis Conference in Philadelphia last week, every third death during the working period of life is caused by pulmonary tuberculosis, and every other workman who becomes incapacitated must ascribe his ruin to this disease. The cost of tuberculosis to the people of the State of New York alone was estimated by Mr. Homer Folks of this city, in a paper read before the Congress, to be $15,000,000 per annum by death and four times that amount by sickness. What is the financial loss to the entire world is beyond computation. The suffering and the sorrow caused by the disease can only be imagined—rather it defies imagination.

It is to free the world from this curse that the crusade against tuberculosis has been inaugurated and is being carried on by earnest workers in every nation on the globe. The triennial congresses, the sixth of which has been in session in Washington this week, are held for the purpose of collecting information regarding the progress of the movement and of encouraging to renewed effort. But their greatest service is perhaps in the publicity which they give to the endeavors of the individual workers and in the awakening of general interest in the crusade. The people, as they read in the papers the reports of the work of the congress, cannot fail to be impressed with the seriousness of the movement and be made to feel that the injunctions against spitting, the warnings against living in dark and unventilated rooms, and all the other hygienic recommendations which are unceasingly dinned into their ears are not the mere preachments of faddists, but are the voices of prophets consecrated to the salvation of the people, crying to them to heed their warnings and be saved.

The international congress which has just met in Washington has done its work well. Among its members were many of the best known and the best phthisiologists of the world who by the fact of their presence and by their contributions to the scientific work of the meeting have stamped the congress as one of the most successful yet held. Not the least important feature of the congress was the exhibition, which is to be continued for yet another week, in which are to be seen plans of sanatoria, hospitals, and dispensaries; appliances for the comfort of the sick; models of out-door sleeping arrangements, of hygienically constructed and furnished houses, railway cars, etc.; educational leaflets for mothers, school children, indoor workers, dairy farmers, and others in all walks of life; pathological and bacteriological specimens, and everything related to the cure or prevention of tuberculosis. A full account of the scientific work of the congress and of the exhibition will be found elsewhere in this issue and in the succeeding one, from which our readers can learn what has been accomplished in furtherance of the warfare against this devastating disease. In this brief comment on the Sixth International Congress on Tuberculosis, however, we cannot omit mention of the work of the Secretary-General, Dr. John S. Fulton, to whom belongs so much of the credit for the success of the gathering. Without the work of him and his assistants, the Congress would not have been what it has been, neither would it have been such without the cordial cooperation of the many workers, lay and medical, who have labored long and earnestly to make this meeting one worthy of the cause and of the country in which it was held.

THE EPIDEMIC OF CHOLERA IN RUSSIA AND IN THE FAR EAST.

WHEN cholera breaks out in the Far East, it spreads like wildfire, for all conditions are favorable to its propagation. Sanitation, as civilized nations understand it, is unknown, food is bad, and the physical state of the majority of the natives predisposes them to the disease. These remarks apply in almost equal degree to the inhabitants of Russia. The population individually may be hardier and more robust than the inhabitants say of India or of Persia, but the sanitary conditions are very similar. Filth indescribable and a total neglect of all precautions to conserve health prevail, and the consequence is that when a disease like cholera gains a foothold it is extremely difficult to dislodge.

Looking at the question from the point of view of the survival of the fittest, by many it may be regarded as an act of Providence that a deadly epidemic disease should from time to time come to sweep away some of the teeming millions of Asia. The countries are overcrowded and there is scarcely food for all, and the people regard death with complacency or apathy, in fact the majority would rather die than live in misery. In India, under British rule, despite the awful and continued ravages of plague, the population has increased and is increasing to such an enormous extent that it has become a source of very serious embarrassment to the government. Again, the natives are by no means grateful for interference to save their lives or to preserve their health. On the contrary they bitterly resent the acts of their rulers in this direction and particularly if such acts clash with the revered tenets of their religion.

This being so, would it not be as well if their conquerors left them to their own devices and did not stretch forth their hands to ward off disease? It might be as well, but it would be contrary to the teachings of civilized races who hold human life in the highest veneration and who look upon its preservation as an act of the supremest importance. Hence, as a rule, one very essential part of the white man's burden is to check the death rate of the natives by every possible means. Of course, selfishness and the instinct of self-preservation count for something, in this crusade made by the white man against disease in faraway lands. If an epidemic rages, the white man is more or less open to its attacks, but, on the whole, the altruistic spirit is the more prominent, and it is to save the life of his brown, yellow or black brother that he labors so untiringly.

In this country our stake in the Far East is scarcely sufficiently realized. Cholera has repeatedly scourged the Philippines and is again present in epidemic form. Our medical and scientific men in those isles are learning the lesson which has been learned long since by the British in India, that it is almost impossible to deal effectively with the natives so far as sanitary matters are concerned. Considering, however, the comparatively short time which has elapsed since the American occupation, immense progress has been made in Manila and elsewhere in "cleaning up" these places. Unfortunately cholera is most difficult to stamp out, as being almost wholly a waterborne disease, and in spite of all the authorities can do the natives will continue to pollute the streams and drink the water unboiled.

One thing, at least, has been definitely learned concerning cholera, and that is that it can be abolished by careful sanitary measures. The malady is no longer to be feared in western Europe, while as for England there has been no epidemic on a large scale since 1866. Although human intercourse and agency are the cardinal factors in the propagation of cholera, if the soil be not favorable the disease will quickly die. Therefore, while care should be observed to keep out the disease, the primary and more important steps to be taken are that conditions favorable to its spread should be absent. If sanitary arrangements are good and water pure cholera cannot gain ground.

THE CANCER PROBLEM.

Two phenomena may be observed in the recent study of the cancer problem that offer a great deal more of promise in solving the vexing questions of the pathogenesis and therapeutics of malignant disease than the numerous scattered attempts at such solution during the preceding epochs. One of these is the establishment of cancer research institutes which offer all the necessary surroundings for carrying on the experimental study of cancer or cancer-like disease of the lower animals as well as for special examinations of specimens of malignant disease aimed at the discovery of any peculiar properties and products of the cellular elements of tumors. The results of such organized study of tumors are already apparent in the knowledge we have gained from the transplantations of tumors in animals and from the many suggestions in reference to the possible control of malignant disease by the influence of enzymes upon the tumor cells. The other phenomenon we refer to is the growing inclination shown by scientific men to attack the cancer problem in the same way as the other biological questions have been studied, that is, by collecting the general data on the subject and by comparing such data with the like findings in other diseases, in a word, by the use of synthetic and comparative methods of research.

Two recent works give evidence of the last-mentioned tendencies in the study of malignant disease: one of them is Menetrier's monograph on "Cancer" in the "Nouveau Traité de Médecine et de Thérapeutique," the other is W. Roger Williams' book on the "Natural History of Cancer." It is Williams' opinion that the prevention of cancer and the reduction of its ravages are the fields of the general problem that offer most hope of productive results at the present time. Accordingly he has gathered a wealth of most instructive information as to the nature and incidence of cancer in the human and animal world. He notes the comparative rarity of the disease among savage races that forms a striking contrast to its wide prevalence among civilized mankind; its greater incidence among the well-nourished, perhaps even over-nourished, classes of the population than among the frugally living classes; the increased liability to disease which appears in groups that are rapidly passing from poverty with consequent insufficiency of food to comparative comfort, as is exemplified by the immigrant classes of the United States; the greater prevalence of the disease in the temperate climate the residents of which use most food of highly stimulating and nutritious character; the increase of cancer which began with the great changes in the economic conditions of the masses of the population in the latter half of the eighteenth century; the comparative rarity of the disease in such countries as Ireland, the bulk of the population in which is decidedly poor and underfed. Among other facts brought out by Mr. Roger Williams is the rarity of malignant disease in wild animals and its occurrence in domesticated animals; the total failure of the adherents of the microbic origin of cancer to bring any evidence worthy of the name in favor of their contention; the warping of facts necessary to trace the origin of all malignant disease to tissue inclusions or embryonal rests that later resume their tendency to grow at the expense of the

general organism. The conclusion, then, of this careful and thorough study of malignant disease, is that cancer is a disease of civilization, probably brought about by the excess of nutrition which stimulates the property of growth present in every cell to an extent beyond the requirements of the organism and results in excessive and disorderly proliferation of the cells. Expressed in most general terms it is the belief of the author that there is a certain relation between the conditions of existence and the incidence of cancer, and the work of prevention of the disease at the present time lies in this direction, at least until more definite data have been presented.

Dr. Menetrier's book is devoted to a different aspect of the subject: he studies the phenomena of malignant disease in the large number of instances of it that he has observed in his capacity of pathologist. To him malignant disease is a morbid process characterized by the "autoinfection of the organism by the cells of the organism;" he sees no great differences between the cancer cells and the other tissue cells: the elements of the organism are capable of increasing and persisting at the expense of the organism just as they are capable of various proliferative, regenerating, and compensating changes. These latter phenomena are the normal functions of the cells, and the cancer process represents the pathological deviation of these functions, just as the thousand and one other perversions of function that may be observed in the morbid states and processes of the animal tissues. These generalizations are founded upon observed facts, and in so far as they show no necessity for presupposing any characteristics in the cells of malignant tumors different from those found in the normal elements of the body they fully justify the endeavor of Roger Williams to find etiological factors in the general surroundings of human beings, especially in alimentation, which may be supposed to exercise most profound influence upon the behavior of the cellular elements of the body.

Neither author, of course, claims to give final conclusions in reference to the etiology and the true character of malignant disease; their works, rather, are suggestive and stimulating in character, and in so far as they call attention to the general factors of malignant disease they serve to counteract the tendency that often crops up in modern highly specialized research work, that of losing the great aspects of the problems under consideration in the mass of details brought forward by the individual investigators.

CARROT SOUP IN INFANT FEEDING.

The reigning controversy in regard to the amount of foodstuffs necessary and advisable for an adult shows how far our knowledge of nutrition is from being an exact science, and still more is this shown when the nutrition of infants is concerned. There are almost as many methods of artificial feeding as there are pediatrists, which certainly would not be the fact if we were sure of the first principles of nutrition. The advance in the so-called "percentage method of feeding," that is, in modifying the separate constitutents of cow's milk according to the age and the individual peculiarities of an infant, has marked one great phase of progress in the latter direction. But modified cow's milk has proved to be no such universal food for infants as its enthusiastic advocates believed in the beginning, and indeed the latest observations have shown that many infants possess great intolerance to cow's milk, however modified, both in health and in disease. It is in such cases that the problem of feeding the child that may be failing in weight and in strength becomes very urgent indeed.

In the *Münchener medizinische Wochenschrift* for August 4, 1908. Dr. Moro of Pfaundler's clinic in Munich urges the use of specially prepared carrot soup for these patients. Infants suffering from acute gastrointestinal disorders, who were usually kept on a strict water diet for several days after the beginning of symptoms, were fed on the carrot soup immediately after the milk was stopped and the results were very gratifying. The symptoms of marked intoxication, the restlessness, the disturbances of consciousness, the changes in respiratory rhythm, the vomiting, and the exhausting diarrhea were quickly subdued by such a diet. A rapid fall of temperature usually followed, and with it the weight curve of the infant again assumed an upward tendency, quickly making up for the loss in weight during the acute attack. After a few days, cow's milk could be given and the interrupted development of the child would again take its natural course. Infants suffering from chronic malnutrition and showing various marantic symptoms improved very markedly on the diet of carrot soup, the gain in weight following the control of the constant vomiting that was a frequent feature of these cases. Clinical observation showed that the retention of water was especially increased by the use of carrot soup and at the same time the fairly high sugar content of the soup was easily borne by patients who could digest no sugar whatever in other preparations. The bacterial flora of the intestines seemed to be very markedly affected in most cases, the usual abundance of Gram-positive organisms present in cases of acute intoxication giving way to a prevalence of Gram-negative bacteria, the total number of organisms being, at the same time, remarkably diminished.

Moro thinks that patients suffering from acute intoxication, with great loss of fluids, and bottle-fed children with chronic malnutrition are best treated by this diet. The latter must never be used or continued with patients who show excessive retention of fluids as manifested by the appearance of edema. Carbohydrate intolerance is likewise not to be treated by the administration of carrot soup. These contraindications leave a vast number of cases in which the new diet may be tried, and such trial is certainly advisable on the strength of the results obtained in the Children's Clinic at Munich.

Street Car Accidents in New York.

Strangers coming to New York frequently accuse us, among other things, of a total disregard for human life. Like most other generalizations this statement is all too sweeping, yet one is bound to admit that it has a foundation in fact for which the most of us are properly ashamed. The very

keen competition in the struggle for existence makes of any large city an abode which is somewhat the reverse of Utopia. Most drivers of moving vehicles from the snail-traveling push cart to the swiftly flying automobile assume for themselves the right of way over all creatures that are obliged to use their legs as a means of locomotion. This is a partial explanation of the fact that in July of the present year, 1,305 persons were knocked down while alighting from street cars. The driver does not figure that when a car stops directly in front of him some one may intend to get off—perhaps he does not use the tramways enough himself to have ascertained that fact, but it is time that the truth were thrust upon him, and that he cease from his reckless ways. The open car with its narrow running board is responsible for many accidents. Any one who rides every day has seen people pushed off who were indulging in the foolish habit of standing on this narrow ledge or in the more foolish habit of trying to get on while the car is in rapid motion. As a result we have these appalling figures for July: Persons killed outright, 35; persons receiving fractured skulls, 13; persons having limbs amputated, 4; persons having limbs fractured, 54. Most accidents are the result of deliberate and wilful carelessness, and the fault is not always with the man who holds the controller. In the hurry-scurry of life in New York people forget danger and miscalculate distances, as well as their agility. The old man of seventy catches at the rear end of a rapidly moving car, the conductor of which is inside, and forthwith somebody is obliged to call an ambulance. Pedestrians take too many chances, and drivers do nothing else. There is a sort of fascination in balancing one's self on the very edge of danger and trusting to overestimated skill or sheer luck for a happy outcome. It is an hypertrophy of this "psychic" element that makes all of our expert "artists" perform their daring feats; yet even they themselves would scarcely question the foolhardiness of these so-called accomplishments. Among four millions of people who must some time or other make use of public conveyances there are bound to be accidents, and many of them, but these accidents should by some means be lessened. Each and all of us need to learn the lesson of making haste slowly. The conductor who slams gates in people's faces and rings his bell before the last foot is aboard his car should receive some greater punishment than that of losing his job or paying a fine. As for "the company," all reasonable excuses offered for delayed cars should be accepted and the present penalties abolished—this would encourage the men to greater civility toward passengers and would lessen the number of accidents materially.

Catarrhal Jaundice and Sugar Metabolism.

It is the growing conviction of both clinicians and pathologists that catarrhal jaundice is not such a simple affection, to be explained by the tumefaction of the duodenal mucosa and the consequent obstruction to the escape of bile at the papilla of Vater, as it has been thought to be. While there is little doubt that icterus may be caused by catarrh of the upper intestines, yet behavior of a great many cases speaks against the possibility of this alone causing prolonged jaundice with the great disturbance of nutrition that is so often observed. Of late, physiological chemistry has given us new data which seem to show that in so-called "catarrhal jaundice" the metabolism of the body is affected much more than has been suspected. Thus Richard Bauer reports in the *Deutsche medizinische Wochenschrift* for August 27, 1908, the results of his study of the excretion of galactose in this condition, which show that the functions of the liver are markedly affected. All the patients suffering from "catarrhal jaundice" showed intolerance to this special form of sugar, excreting it in much greater degree than normal after the administration of a uniform amount, such intolerance continuing not only during the manifestations of the disease, but even for several weeks after all symptoms of jaundice and of intestinal catarrh had disappeared. Patients suffering from jaundice caused by obstruction of the common gall-duct by a stone did not show this phenomenon, nor could it be demonstrated in malignant disease of the bile passages. Cirrhosis of the liver, on the other hand, seemed to have the same effect upon metabolism, and it is, of course, granted that in this disease the functions of the liver are markedly impaired. Pathological conditions involving the gastrointestinal tract similar to such as are supposed to result in catarrhal jaundice were likewise not accompanied by this phenomenon, and consequently the supposition that an additional factor must be present in jaundice is well supported. What the real nature of this factor may be remains to be shown, but the presence of alimentary glycosuria in catarrhal jaundice, beyond being an important fact in the differential diagnosis of this condition from malignant disease and from obstruction by gallstones, points to the liver as the site of the important disturbance, whether functional or anatomical and not to the gastrointestinal tract.

Lactic Acid Bacteria for the Relief of Constipation.

Constipation is one of the troubles that we have with us always, and for which the remedies are legion. Yet most of these remedies have proved unsatisfactory in the end because their effect was but temporary and the result of treatment was paresis of the intestine. One of the modern forms of treatment is by means of cultures of lactic acid bacteria. Gaillard, in the *Journal de Médecine de Paris*, for August 8, 1908, details his method of treatment and gives the histories of ten cases treated with lactic acid bacteria as an adjuvant to a change in diet. Constipation, according to this author, is closely linked with autointoxication, the decomposition of albuminoids particularly ending in the formation of toxic materials. Antagonistic to this is the action of the bacteria which act on the vegetable compounds, and which produce antiseptic compounds in the form of organic acids, such as lactic and acetic acids. The author begins his treatment by placing the patient on a diet that includes vegetable gruels made with milk, potatoes, eggs, and small quantities of meat. He thus encourages the proliferation of the amylolytic microbes which are useful, at the expense of the proteolytic organisms, which are harmful. The patient is also given a bouillon culture of lactic acid bacteria, which by its action produces antisepsis. As soon as the digestion has been regulated in this way defecation occurs with regularity without other treatment. In the ten cases treated by this method the results were in the main favorable, there having been four undoubted cures. In some of the patients there was produced at first a crisis of enteritis, and this was repeated in one case whenever the medication was attempted. The method is worthy of further study and experiment, based as it is on rational theories.

News of the Week.

Wesley M. Carpenter Lecture of the New York Academy of Music.—On Thursday, October 8, 1908, at 8.30 P.M., the Wesley M. Carpenter lecture upon "Tuberculosis of the Heart, Blood Vessels, and Lymphatics" will be given by Dr. Andres Martinez-Vargas of Barcelona, Spain. The lecture will be in Spanish, but a pamphlet with the English translation will be presented to every person in the audience so that the lecturer can be readily followed. After this lecture there will be a reception by the President and Fellows of the New York Academy of Medicine and the Committee on Entertainment of the International Congress on Tuberculosis to the visiting members and delegates of the Congress.

Cholera in Manila and St. Petersburg.—The situation in St. Petersburg is said to be greatly improved. Provision for the care of the sick has been made by converting several public schools into hospitals, and official steps have been taken for the distribution of medicines and disinfectants, but there has been considerable delay in interring the dead. Since the outbreak of the disease up to September 27, there had been in St. Petersburg 4,945 cases and 1,875 deaths. In the rest of the country the cases numbered 10,857, and the deaths 5,226. Russian emigrants to America are detained at Hamburg for five days before embarkation as a precaution against the spread of cholera. The outbreak of the disease in the Philippines has caused considerable discussion as to the risk of allowing the fleet now on its way there to touch at Manila, and preparations for a formal welcome which were being made by the city have been postponed. The situation in the islands is, however, rapidly improving.

New Tuberculosis Hospital.—Plans were filed on September 25 for the new hospital building to be erected on Blackwell's Island for the treatment of cases of tuberculosis in conjunction with the other city institutions. The building will be 291 feet long and four stories high, with wide verandas surrounding each story. There will be a roof garden over the entire length of the building with a solarium at either end. The local island stone will be used with bluestone trimmings. The estimated cost is $250,000.

The Chicago Tuberculosis Sanatorium, located at Winfield, on an elevation fronting the DuPage River, will be opened in a short time. The head of the medical staff is Dr. Theodore Sachs. The institution was established under the auspices of the women of the Chicago Jewish Club.

Insane in Maryland. Figures recently published indicate that the State of Maryland has fewer insane persons in proportion to its population than any other State in the union. There are at present only 3,200 insane people in public and private institutions in Maryland, as against 11,000 in Massachusetts, and even larger numbers in some of the other States. There is at present no State care of the insane in Maryland. Those unable to pay for treatment are cared for in semi-public and private institutions, some of which receive State aid. Notwithstanding the small number, every institution in the State is overcrowded, and this lack of facilities has caused a general investigation of the problem, and the State will probably soon undertake to provide for all cases.

The College of Physicians and Surgeons, Columbia University, New York, opened on September 23 with a registration in all classes of 290, which number, however, will probably be somewhat increased later. The first year class numbers 90, and of these twelve students are seniors and juniors from Columbia College who have elected the course. The opening exercises were held on September 24, when addresses of welcome were delivered by Professor Burgess, acting president, and Dean Samuel W. Lambert. Professor M. Allen Starr, of the department of Neurology, also addressed the students on "The Duty of the Medical Profession to the Public."

Opening Exercises of the Chicago College of Physicians and Surgeons.—The twenty-seventh annual course of instruction of the College of Physicians and Surgeons, Medical Department of the University of Illinois, began September 28, at which time the introductory address was delivered by Professor Channing W. Barrett.

Civil Service Examinations for the positions of assistant in clinical psychiatry at a salary of $2,000; health officer, town of Wells, Hamilton county, and physician, sixth grade, for State hospitals and institutions, $900 and maintenance, will be held by the New York State Civil Service Commission on October 17, 1908. The last day for filing applications for these positions is October 10. Full information and application forms can be obtained upon request to the Chief Examiner of the Commission at Albany.

New York's Death Rate.—For the week ending September 19, the figures were 15.46 deaths per 1,000 of population, the total number of deaths being 1,311. For the same week last year the rate was 16.73, and the total number 1,374. Among children under five years of age there were, during this week, 538 deaths in 1907, and 480 deaths in 1908. Among children under the age of one year the number of deaths was 388 in 1907, and 348 in 1908.

Flies and Disease.—Dr. Daniel D. Jackson, of the Merchants' Association Committee on Water Pollution, has been trapping flies during this summer at a station near Prospect Park, Brooklyn, and comparing the record of his captures with that of last year and with the Health Department mortality figures, to verify the theory that flies and not hot weather are responsible for the prevalence of intestinal diseases. He reports the relation between the number of flies captured and the number of deaths substantially the same as last year, the highest death rates occurring at the same time as the largest catch of flies, and a decrease in the number of flies being accompanied by a fall in the rate. Dr. Jackson thinks that the education which the people have had in the last year in regard to the dissemination of disease by flies has probably had a share in keeping the death rate down during the summer of 1908.

Charitable Bequests.—The Massachusetts General Hospital and the McLean Insane Hospital of Boston each receive $50,000 under the will of the late George F. Parkman of that city. Among other bequests are $40,000 for the Newport Hospital, $20,000 for the Female Orphan Asylum, $20,000 for the Children's Island Sanatorium, and $10,000 for the Boston Floating Hospital. The residue of the estate is left to the city of Boston, the income to be used for the improvement and maintenance of public parks. The will of the late Jonathan J. Broome of New York and East Orange provides for the gift of $2,500 to the Orange Memorial Hospital, and of $500 to the Record Ambulance, of Orange. The Floating Hospital of St. John's Guild benefits to the amount of $10,000 under the will of the late Henry J. Braker of New York. A number of institutions profit under the will of the late Winfield Tucker of

New York. The Presbyterian Hospital is to receive $22,500 to endow three beds in perpetuity, the Fresh Air and Convalescent Home at Summit, N. J., $3,000, and $5,000 each is left to the Post Graduate Medical School and Hospital, the New York Throat, Nose and Lung Hospital, and the House of Rest for Consumptives at Inwood-on-the-Hudson.

To Rebuild Hospital.—St. Mary's Hospital, at Orange, N. J., is to be enlarged by the addition of a six-story extension, to cost $60,000. The new building is a part of a general plan for the practical rebuilding of the institution, the cost of which will probably be about $200,000. The popular "tag day" idea is to be used to raise funds for the work, and October 3 is the date selected. The new building will contain a basement kitchen, dining-room for convalescents, and staff-rooms on the first floor, children's wards on the second floor, and wards for men and women on the third and fourth floors. The fifth floor will be devoted to the maternity ward, and the top floor to operating rooms. There will also be a roof garden which can be reached by the elevator.

Jewish Hospital to be Erected.—Orthodox Jews in Chicago have organized an association, licensed as Miamonides Kosher Hospital Association, to erect and maintain a Jewish hospital. About $10,000 has been subscribed already, and a permanent building will be erected. It is proposed to carry out the orthodox Hebrew dietary laws and habits in the institution.

School Inspection.—Seven hundred pupils of the Chicago public schools were barred from attendance during the last week, the result of examination by medical inspectors. Less than 10 of these had symptoms of contagious disease, but many had parasitic diseases.

Sixteenth Year of Pasteurization.—September 21 marked the completion of the sixteenth year of Mr. Straus's work of dispensing pasteurized milk to the poor. During the past year there has been a large and steady increase in the use of the milk which is sold at less than cost at seventeen stations in New York, and it is estimated that nearly 2,500 babies have been fed daily on the output from these stations.

Illinois Health Commission Named.—Governor Deneen of Illinois has appointed a commission to investigate and report upon the most advisable methods for providing for the health, safety, and comfort of employees of public and private institutions, in accordance with a joint resolution passed by the Illinois Legislature.

Cocaine Sellers Sentenced.—Two men, frequenters of Chinatown in New York, who were recently convicted of selling cocaine in this district, were sentenced on September 23 to one year each in the penitentiary by Judge Malone. "The crime must be stopped," the judge is quoted as saying, "and the only effective way is to send cocaine sellers to jail."

Dr. Wilhelm Karo, of Berlin, Germany, read a paper on Tuberculosis of the Bladder at a meeting of the Richmond (Va.) Academy of Medicine and Surgery on September 22.

Dr. Morton Prince, professor of nervous diseases at Tufts College Medical School, will give a course of lectures at the college on the value of mental suggestion in forms of nervous depression and similar affections. The new course is said to be largely due to the Emmanuel Church movement.

Dr. Daniel W. Finnimore, of Potsdam, N. Y., a graduate of Fort Wayne Medical School in the class of 1881, has been nominated for the office of Lieutenant-Governor of New York, on the ticket of the Independence Party.

The American Electro-Therapeutic Association.—At the eighteenth annual meeting of this Association, held September 22 to 24, at the Engineering Societies Building, New York City, the following officers were elected: *President*, Dr. Edward C. Titus of New York; *Vice-presidents*, Drs. William D. McFee of Haverhill, Mass., and Thomas D. Crothers of Hartford, Conn.; *Secretary*, Dr. J. W. Travell of New York; *Treasurer*, Dr. Richard Joseph Nunn of Savannah, Ga.; *Executive Council*, Drs. Morris W. Brinkmann of New York, Charles Rae Dickson of Toronto, Canada, W. Benham Snow of New York, Fred H. Morse of Boston, Herbert F. Pitcher of Haverhill, Mass., and Francis B. Bishop of Washington, D. C.

American Dermatological Association.—At the meeting of this Association, held at Annapolis and Baltimore, September 24, 25, and 26, 1908, the following officers were elected for the ensuing year: *President*, Dr. William Thomas Gilcrist of Baltimore; *Vice-president*, Dr. William Allen Pusey of Chicago; *Secretary and Treasurer*, Dr. Grover William Wende of Buffalo. The next meeting of the Association is to be held in Philadelphia in May or June, 1909.

The National Wholesale Druggists' Association held its thirty-fourth annual convention at Atlantic City on September 21 to 25. Some opposition was made to the recommendation that the United States Pharmacopeia be issued every five years instead of every ten, as has been the custom, but the Association finally decided in favor of the five year plan. Dr. F. L. Carter of Boston was elected president for the coming year, and Mr. J. E. Toms of New York, secretary. The next convention will be held in Richmond, Va.

The Washington State Medical Association held its annual convention at Walla Walla during the second week in September. The following officers were elected for the coming year: *President*, C. A. Smith, Seattle; *Vice-president*, Y. C. Blalock, Walla Walla; *Second Vice-president*, W. D. Kilpatrick, Bellingham; *Secretary*, C. H. Thompson, Seattle; *Treasurer*, L. L. Love, Tacoma; *Delegate to American Medical Association*, J. R. Wenn, Tacoma; *Alternate*, H. H. McCarthy, Spokane. Plans were made for holding the next annual meeting in Seattle in July, 1909, in association with the State societies of Oregon, Idaho, and British Columbia.

New York and New England Association of Railway Surgeons.—The eighteenth annual meeting of this Association will be held at the Academy of Medicine, New York City, on November 17, and 18, 1908, under the Presidency of Dr. F. A. Stillings of Concord, N. H. The morning session of the first day will be devoted to a symposium on "What Are the Causes Leading to Railway Accidents and What Remedies Can Be Suggested?" The secretary of the Association is Dr. George Chaffee, 338 Forty-seventh street, Brooklyn, N. Y.

Obituary Notes.—Dr. John A. Hegeman of New York died suddenly at his home on September 23, aged 56 years. Dr. Hegeman was graduated from the College of Physicians and Surgeons of New York in 1879 and practised in Passaic, N. J., until three years ago, when he retired to enter into business life.

Dr. J. C. Driver of Atlanta, Ind., died at his home on September 16, from cancer, aged 76 years. Dr. Driver was graduated from the medical department of the University of Michigan in 1866 and was the oldest physician in his county.

Dr. Neal O'Donnell Parks of Ashton, Mass., died suddenly at his home on September 17. Dr. Parks was born in Ireland, and graduated from the medical school of the University of Dublin in 1859, coming to this country a few years later. He was the author of a number of books and magazine articles.

Dr. Charles H. Osgood of Cincinnati, O., died on September 12, aged 78 years. Dr. Osgood was a veteran of the Civil War.

Dr. Zophar F. Guerin of Columbus, O., died suddenly on September 15, aged 87 years. Dr. Guerin had been a practising physician since his graduation from Starling Medical College in 1852.

Dr. Claudius R. Grosser died at Wilkes-Barre, Pa., on September 24. He was graduated from the medical department of the University of Pennsylvania in the class of 1898.

Dr. Clark Evans, formerly a resident physician at Jefferson Hospital, Philadelphia, died at Lehighton, Pa., on September 26 at the age of 26 years. He was graduated from Jefferson Medical College in the class of 1906 and he was for a time assistant physician at the White Haven Sanitarium.

Dr. Philip L. Reichard died at Allentown, Pa., on September 26, at the age of 65 years, in consequence of a fall resulting from an attack of vertigo. He was graduated from Jefferson Medical College in the class of 1864. He was an army surgeon during the Civil War, was for many years pension examiner, and for a long period local surgeon for the Lehigh Valley Railroad Company.

OUR LONDON LETTER.

(From Our Special Correspondent.)

SCIENCE AT DUBLIN—PHYSIOLOGY—HALDANE'S ADDRESS—TUBERCULOSIS IN IRELAND—SLEEPING SICKNESS—CHOREA, A SPECIFIC—LUNACY REPORT—GOVERNMENT SCIENCE GRANTS—UGANDA—OBITUARY.

London, September 11, 1908.

Dublin's feast of science is over. Some few are endeavoring to form an opinion as to the probable results, but it is too soon for such speculation. One can hardly say much even of the impression produced by the president's address, of which I sent you a brief sketch. It was looked forward to with unusual interest, and certainly Dr. Darwin did not disappoint those who expected he would make some further application of his father's theory in opposition to more recent views. Whether his statement that plants form habits, and that implies a sort of memory, will obtain general acceptance remains to be seen. At present there does not seem much inclination to discuss the matter. But perhaps that is largely due to the wealth of material provided by the sections. Some of these are of general interest and touch on the daily life, occupation, health, and even political progress of the nation. I can therefore only allude to some of the more strictly scientific subjects closely connected with medicine.

In the physiological section Dr. J. S. Haldane, F.R.S., delivered the address, in which he contended that biological phenomena differ not only in complexity, but also in kind from chemical and physical processes. He declared that the conceptions of physics and chemistry cannot make physiological phenomena intelligible. The problem is not to obtain piecemeal explanations, but to discover by observation and experiment the relatedness to one another of all the details of structure and activity in each organism as expressions of its nature. One example of the necessity of such research was a subject on which he had been working, viz., the regulation of respiration. On this he said: "Current accounts of the clock-like action of the respiratory center during normal breathing, with the expansion and contraction of the lungs acting as a sort of governor through the vagus nerves, always filled me with suspicion, as it seemed to me that such a regulation was altogether unlike a physiological one. This led me to investigate the matter further, along with Mr. Priestley, and we had the satisfaction of being able to prove that the ventilation of the lungs is actually regulated with exquisite exactness, in such a way as to keep the partial pressure of carbon dioxide in the alveolar air, and, presumably, in the arterial blood, constant. In reality, therefore, the lung ventilation is regulated in accordance with the requirements of respiratory exchange, and what seems the true physiological explanation has been advanced a short stage." Similar evidence is accumulating in all directions that the blood supply to various parts is determined by their physiological requirements. So it seems clear we are only at the beginning of a vast development of our knowledge in this direction, for which far more refined methods of dealing with the chemistry of the body will be needed. Further, the president held that as our attitude toward biology has changed so it must toward evolution. Our conception of an organism is different in kind as well as degree from that of a material aggregate, therefore in tracing back life to primitive forms we can get no nearer to what is called a biogenesis. That is, only to widen biological ideas. In short, we must not aim at reducing organic and inorganic, but at bringing inorganic phenomena into the domain of biology. In conclusion Dr. Haldane referred to the relation of physiology to psychology, and remarked that the higher organisms at any rate are conscious and intelligent and "just as biology is something more than physics and chemistry, so psychology is something more than physiology, with the added assumption that consciousness is tacked on to certain physiological processes, if such a crude conception has any definite meaning." Treating sensation as the physiology of the sense organs is physiology, but nothing else, as it leaves out the elements of consciousness. "Life is not intelligence and men or animals as intelligent individuals involve a deeper aspect of reality than biology deals with. Our fundamental physiological working hypothesis cannot be successfully applied to the phenomena of intelligence, and the sooner and more definitely this is realized the better for physiology."

The Earl of Aberdeen (Lord Lieutenant) was present in the Physiological Section on Tuesday to hear an address by Sir Robert E. Mathieson, Registrar-General for Ireland on the antitubercle crusade initiated by the Countess. This special meeting was naturally largely attended, and on the proposal of Dr. F. Darwin Lord Aberdeen took the chair and expressed the satisfaction of the Countess at the subject being brought before the association. Sir Robert set forth the problem of tuberculosis in Ireland and detailed the history of what has been done. Some of the results are a notable change in the habits of the people as to open windows and cleanliness, a decrease in the habit of spitting, a recognition by mothers of the unsuitability of white bread and tea as food for growing children, the substitution of home-made bread, porridge, milk, or vegetables, greater care by local authorities as to milk supply, segregation of advanced cases, provision of district nurses, disinfection of houses after deaths, scavenging the streets, and water supply.

Professor E. J. McWeeney, who has been lecturing during the crusade, testified to the enthusiasm of the people addressed in various parts of the country, and in this he was corroborated by his colleagues in subsequent speeches.

Sleeping sickness was discussed in this section in conjunction with that of zoology. Dr. Nickenstein gave an account of his researches on atoxyl and said he was driven to the conclusion that while it is very successful in the case of some animals, it is useless in others. Experiments with the trypanosomes taken from a donkey which had been treated by atoxyl showed this. Professor Moore considered this result important and related an experiment on two sets of rats, one set treated with atoxyl, the other with mercury. The former all died, but 50 to 60 per cent. of the latter recovered. He inferred that the parasites could be attacked with mercury when atoxyl failed. He suggested arsenic and antimony in combination. Dr. Breinl narrated the life history of the trypanosome and said when it disappears from the blood under atoxyl minute bodies may be found in the spleen, which develop into the parasite when the antibodies disappear from the blood.

Dr. Essex Wynter thinks that chorea is as certainly amenable to treatment by chloretone as rheumatism is by salicylates. He read a paper at Sheffield relating 50 cases of different degrees of severity. Some showed only disorderly movements, some could not speak or feed themselves, and for a few padded cots had to be used on account of the violent movements. The dura-

tion before admission to hospital had varied from a few days to months and in one case three years. The majority were first attacks, but there were some second, third, and fourth. Chloretone is trichlor-tertiary-butyl-alcohol and has been introduced for some time as a sedative to the central nervous system, but non-depressor of the circulation or respiration. Dr. Wynter gives 5 grains in half an ounce of petroleum emulsion every four, six or eight hours, according to the patient's age and the severity of the symptoms. In two, three or four days the dose is to be reduced by half and may be given less frequently. In the 50 cases the average duration of treatment was nine days. In many, movements ceased in four, six or seven days, in a few not for twelve or more. These last had resisted other remedies for long periods, three or four months, a year or more, six for three years. About half the children had cardiac disease, but the average stay in hospital was only three weeks. After the chloretone had subdued the movements, iron, cod liver oil or arsenic was prescribed, as seemed indicated, and the patients were under observation for a further three weeks in the convalescent home. If continued too long or given in too large doses chloretone will cause stupor and occasionally a condition resembling catalepsy. This passes off in a few hours, but may easily excite the anxiety of friends. One or two cases had a punctiform erythema and two others desquamation of hands and feet. Only one relapse occurred. Laxatives increased the effect of the chloretone, probably by stimulating absorption. The rest in bed and diet were admitted as important adjuncts.

The report of the Lunacy Commissioners, issued a few days ago, shows that on January 1 the certified insane under care in England and Wales numbered 126,084, an increase of 2,096 over the number at the same date last year. The annual increase for the last ten years averaged 2,411. There has been for some time an increasing proportion of lunatics cared for in county and borough asylums, and these institutions now contain about three-fourths of the total number. Concomitantly there has been a decrease in the number treated in pauper institutions and in private licensed houses.

In the county of London we have an increase of 410 as compared with that of 356 in the preceding year.

Nearly three-fourths of these annually certified as insane are in their first attack. The remainder are recurrent cases. The commissioners think that in some future time convalescent homes may be established and result in a decrease of the readmissions. At present there is the after cure association, but its scope is very limited. The commissioners say that if it received the support it deserves it would contribute to a real decrease in the insanity in this country.

Colonel Sir David Bruce, M.D., is about to visit Uganda to inquire further into sleeping sickness on behalf of the Army Medical Advisory Board.

The Local Government Board has completed the allocation of the scientific grant for 1908-9 by authorizing the following researches in addition to those of which I have previously informed you: (1) By C. G. Moor, M.A., and Dr. Hewlett as to the influence of softening and other chemical processes on the purity of water supplies from chalk; (2) production of disease by certain streptococci and poisonous substances produced by them. This research is to be by Professor Sidney Martin, F.R.S.

The Dublin University took the opportunity of the meeting of the British Association to confer the degree of D.Sc. on the President, F. Darwin, and on Professors Sherrington, Macullum, and Kossel.

Among recent deaths in the profession are two nonogenarians. Dr. Lightfoot, formerly of Newcastle-on-Tyne, in his 94th year, died on August 27, and Dr. John Taylor, well known in Essex, on September 4, aged 90.

Dr. F. H. Alderson, J.P., of Hammersmith, on the 3d inst., in his 70th year.

Dr. Alex. Louis Achard, on the 4th inst., aged 46.

Lieutenant H. A. Knight, M.B., I.M.S., on the 4th, aged 28.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

MEETING OF THE MANILA MEDICAL SOCIETY—ANEURYSM OF THE AORTA—TREATMENT OF THE OPIUM HABIT—INTESTINAL BILHARZIOSIS—THE CHOLERA SITUATION—CURE OF LEPROSY BY X-RAYS.

MANILA, P. I., August 15, 1908.

THE first meeting of the Manila Medical Society since the recess which was taken during the hot season took place at the Philippine Medical School building on Monday evening, August 3. Among the pathological specimens shown was an aorta which had ruptured into the esophagus. The clinical history showed that no symptoms of the aneurysm were found during life in spite of the fact that the patient had complained of a pain located deep in the chest at about the fifth rib, and he had been physically examined by a number of different medical officers. In this connection Major Borden related a case in which the patient had been an unusually robust man and presented no physical symptoms of disease. One day he became intensely cyanosed, especially about the head, neck and face, and died several hours afterward. The autopsy showed that an aneurysm of the aorta had ruptured into the vena cava. The first paper of the evening, entitled "The Treatment of the Opium Habit at the San Lazaro Hospital," by Dr. A. S. Rochester, was read by the secretary. The treatment of over 300 cases was reported, practically all Chinese, who came under observation as the result of the "Opium Law," which went into effect last March. An analysis of the cases showed that nine-tenths of them had been using the drug by the means of a pipe and that these were able to give up the habit with little difficulty; those who used the drug by mouth suffered somewhat more upon its withdrawal, and those who used it hypodermically suffered the most, but in no case was a period longer than ten days required to enable any case to give up the drug entirely. The treatment used was the gradual withdrawal method. Upon arrival at the hospital the cases were admitted to a receiving ward, where they were kept a sufficient time to enable them to be searched a number of times for any opium or its derivatives that might be secreted. In the case of Chinese, opium or morphine was found a number of times in the hair of the patient. The gradual reduction of the daily dose was then begun; those who suffered no severe symptoms were transferred to a separate ward and placed under the charge of reliable attendants. Those who were more severely affected were transferred to a separate ward where American women trained nurses were in charge. As soon as possible—usually within three or four days—the cases were transferred to the convalescent ward, where no opium of any kind was given, and if no symptoms manifested themselves they were discharged ten days after they reached this ward. The impression produced upon the writer was that the smoking of opium by Chinamen produced no more symptoms or serious effects than the use of alcohol in moderate quantities did in the white race and that the habit was given up with equal ease.

The next paper, entitled "A Case of Intestinal Bilharziosis," by Dr. G. W. Jackson, was most important on account of the fact that it was the first case of bilharzia that has been reported from the Philippine Islands. The patient was a soldier and had only been in the Philippines for about one year; previous to that he lived at a number of different places in the United States, none of which are known to be infected with this parasite. However, more than four years ago he lived in Porto Rico, which is known to be infected. During the past few months he has been afflicted with amebic dysentery, and a few weeks ago, while making routine stool examinations at the army hospital at Fort McKinley at which the patient was confined, the eggs of the bilharzia parasite were detected. Specimens of the same were demonstrated at the meeting. A most interesting discussion followed, in which the Chief Surgeon of the Philippine Division, Colonel Hoff, and the Director of Health, Dr. Heiser, took part. The great importance of such a case to the public health in a community which had all of the necessary factors for propagating the infection and in which it had not yet been introduced, was clearly brought out, and the consensus of opinion was that such a case should be rigidly isolated, and if at all practicable a person so afflicted should leave the islands for a colder climate, which would give the patient a better chance of recovery and at the same time remove the danger of infecting the Philippines.

The cholera situation in the Philippines remains about the same. The average number of cases is still about 150 per day, as the disease slowly disappears in those sections in which it appeared originally, it is gradually spreading to other portions of the islands. So far the disease has spread entirely by land, the cases that were carried by vessels having been promptly detected and the infection eradicated. In the provinces there has been no difficulty in tracing the infection from person to person, while in the city of Manila, a number of cases have occurred in which it has been impossible to trace any connection whatsoever with any other case.

In the annual report of the Bureau of Health for the fiscal year ended December 30, 1908, another case of leprosy cured by the *x*-ray is reported.

OUR LETTER FROM COPENHAGEN.

(From Our Special Correspondent.)

MODE OF EXCRETION OF ATOXYL—HIGH-FREQUENCY CURRENTS IN NERVOUS DISEASES—PEPTIC ULCER OF THE JEJUNUM—SMALLPOX IN CHRISTIANIA.

COPENHAGEN, August 31, 1908.

At a meeting of the Swedish Medical Society Mr. A. Blomquist read a paper on the excretion of atoxyl after subcutaneous injection. Professor Welander had tried the atoxyl treatment of syphilis and had prompted the speaker to investigate the excretion of this new drug. It turned out that the atoxyl passed through the organism without being altered, which fact explained how such large doses as 60 centigrams could be administered without hurt to the patient. Of such a dose one generally found 60 or 70 per cent. again in the urine passed during the first twenty-four hours after the injection. Very small quantities only could be demonstrated in the urine for the subsequent fifteen to twenty days. Very little was also found in the feces, and the sudoriferous glands did not in all probability play a greater rôle in the excretion. The question, what had become of the quantity of the injected atoxyl, which could not be found again in the urine, was solved by examination of the blood, in which a relatively large amount was retained for a long time. Only freshly made solutions of atoxyl ought to be employed, as older solutions are apt to become moldy. Professor Welander considers the action of atoxyl on syphilis as uncertain, and opines that in those cases in which the atoxyl has shown a curative effect better results would doubtless have been attained by the use of hydrargyrum and potassium iodide. Professor Edgren had tried atoxyl in pernicious anemia without result. He drew attention to the fact proved by Mr. Blomquist's researches that atoxyl did not act as an arsenic preparation, as it passed through the organism without being decomposed in its constituents. It was consequently a mistake to use atoxyl in cases in which arsenic was indicated, though several authors had been misled to do so by the seeming possibility of introducing very large quantities of arsenic into the organism without danger.

At a meeting of the Copenhagen Medical Society Dr. V. Christiansen read a paper on the use of electric currents of high frequency and tension in nervous diseases. He had tried the treatment in 121 patients, 56 of whom were suffering from functional diseases of the nervous system, while the disorder was of an organic nature in the rest of the cases. His opinion was that the neurologist possessed a useful means of suggestion in the high-frequency current. They were successful in certain cases of insomnia and had proved useful in rooting out hypnotic drug habits. Finally, they had been able to relieve painful attacks, except those found in hysteria and in locomotor ataxia. Dr. Fischer said he had used the treatment since 1901 and had found it very helpful, perhaps not so much in neuralgia as in cases of insomnia and mental depression. Even if suggestion might explain much of the efficacy of the method, he did not think that the successful results could be ascribed totally to suggestion. Professor Friedenreich was very much pleased by the sound skepticism expressed by the two previous speakers. That the Tesla current proved useful in such cases as mentioned could not be doubted. But those were exactly the same cases in which formerly static, galvanic, or faradic electricity was employed with success, and of which Möbius had truly said that the result was due in three-fourths of the patients to autosuggestion.

At the same meeting Dr. Jörgen Jensen read a paper on peptic ulcer of the jejunum. This rare complication of a gastroenteroanastomosis presented a very great danger to the patient, because the ulcer might perforate and produce a fatal peritonitis. It would therefore be well to perform a pylorectomy or a gastroduodenostomy in those cases of ulcer of the stomach, where such operations were feasible, and only employ the gastroenterostomy in the remaining cases. Dr. Ernst had had a case of the mentioned jejunal ulcer under treatment. On operation he found at the site of the gastroenteroanastomosis an irregular ulcerous tumor and performed, therefore, an enteroenterostomy below the previously existing anastomosis. The patient had remained cured for more than a year, probably because the ulcerous tumor was now less irritated by the sour contents of the stomach. Professor Th. Rovsing had always fought against the excessive use of gastroenterostomy in gastric ulcer and agreed with Dr. Jensen that the ulcer ought to be extirpated in all suitable cases. Judging after his own operative experience, he did not think that the mortality should be higher than after gastroenterostomy.

In Christiania an epidemic of smallpox has created not a little sensation among the public. Nearly the whole population of the town has been revaccinated, and there are signs that the epidemic has already culminated. About one hundred patients are suffering from the disease. Only very few deaths have occurred.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 17, 1908.

Analysis of the Symptoms in Forty Cases of Suppuration of the Pelvis of the Kidney.—A. L. Chute reviews his own experience. He admits that the tabulation of a larger number of cases might give somewhat different percentage figures. He finds that of his own cases, less than one-half (42.5 per cent.) with a history of lumbar pain, or a little over one-quarter (28.5 per cent.) could he detect any enlargement of the diseased kidney. Tenderness was present in 38.5 per cent. Casts appeared in 17.5 per cent. Eleven of the forty cases (27.5 per cent.) presented neither pain, appreciable renal mass, tenderness, or casts. The constant sign is the turbid urine. His next most frequent sign is a disturbance in micturition (85 per cent.). Both these symptoms also occur almost constantly in conditions limited to the bladder. In this particular series in 27.5 per cent. only these two signs were present. In view of the lack of distinctive symptoms in many renal suppurations and the absolute unreliability of negative findings in these cases, the vast importance of cystoscopy in the study of urinary suppurations is at once obvious.

Non-Tuberculous Bone Infections About the Hip Joint a Clinical and Roentgenological Study.—A. T. Legg and A. W. George present the histories of ten cases adding an excellent collection of radiographs. The authors believe that many cases treated as hip-joint tuberculosis are really not such, but rather suppurative processes pure and simple. As surgery offers the possibility of a complete cure, early recognition is most desirable. The series of cases here offered are instances of pyogenic infections producing acute or chronic osteomyelitis. Such cases constitute about one-seventh of all cases of hip disease. Clinically, the symptoms of acute pyogenic infections *outside* the hip-joint, namely, acute onset, rapid thickening of the neck, trochanter or upper shaft, pain, spasm, and constitutional symptoms with high white count, will generally easily differentiate this class from tuberculosis. The differential diagnosis of the chronic cases, those produced by a low-grade organism, is, however, much more difficult from a clinical standpoint. The deformity, limitation of motion, spasm, and atrophy may be the same as that seen in tuberculosis of the hip. Thickening is felt earlier than in tuberculosis and the white count is considerably higher than we find in uncomplicated tuberculosis. There may be no more constitutional symptoms in this class of cases than is seen in tuberculosis. Of all points in the physical examination of cases referable to the hip-joint, *rotation* is of the greatest importance. In cases with a focus outside the hip-joint, rotation may be free, limited, or even absent. If any is present, however, it will have the normal quality, while, where any change has taken place in the articular cartilage, the rotation, if present, has a peculiar characteristic quality. In the acute pyogenic infections *within* the joint we have classical symptoms of acute joint infection, acute onset, rapid joint distention, pain, constitutional disturbance, and high white count. The sub-acute or chronic cases, those starting in the epiphyseal line or as a general joint infection, may differ in no respect clinically from tuberculous hip disease. These will generally clear up much earlier than tuberculosis, with possible perfect function. This type will show an ultimate permanent lengthening from the irritation of the epiphyseal cartilage. Of course, secondary pyogenic infection may follow a primary tuberculous lesion.

New York Medical Journal, September 19, 1908.

Bacterial Treatment of Erysipelas.—H. A. Duncan and G. M. Illman report three successful cases. The dose varied from thirty to sixty millions dead streptococci. In the first case the fever dropped in twelve hours and re-

covery after was uneventful. In the second case the treatment was given on the morning of the third day of the disease and in twenty-four hours the temperature was nearly normal. In the third case, the disease was ushered in by an angina and later the usual facial symptoms were present. Some slight improvement was noted for two or three days, but later the disease took an unfavorable turn and the erysipelatous inflammation spread down as far as the mammæ. In the latter part of the second week, an injection of streptococci was given. Some reaction was noted on the day following. There was a considerable remission in temperature on the second day. No further extension of the inflammation occurred on the chest, and there was a marked drop in the temperature, with no subsequent rise. The temperature was 99.2 degrees F. on the third day. Some extension of the inflammation occurred on the arms, but no further rise of temperature was noted. The temperature was normal on the fourth day, and there was no further extension of the inflammation. Recovery was uneventful. The author admits the futility of drawing lessons from merely three cases, and reports them only for their face value, hoping that others will follow the same therapy and publish their results.

Psychotherapy.—A. M. Stuart says that every skillful physician must be a mind healer or he will not succeed, no matter how great his knowledge of disease. He considers the patient's mind in everything he says and does. The author discusses the mental healing of Mesmer and the more accurate and scientific work of Charcot. He then considers the Emanuel Church movement and the work of Dubois of Bern. The latter he considers as superficial and non-scientific. "He has an eye for just one thing—a neurosis. He admits that even if he discovers tuberculosis he ignores it, because otherwise he would weaken his power of cheerful suggestion. * * * He objects to methods of exact diagnosis on the ground of their increasing the fixed ideas of the patients. He admits the necessity of surgery for appendicitis and similarly serious troubles, but he scoffs at medication, calling it a bungling form of suggestion, practised because the public has been trained to it. The effect on the general public of this latest claim on the part of the clergy of the power to cure disease by suggestion is, the author thinks, liable to lead to a most unfortunate state of mind on the part of the general public, who will lose its faith in legitimate medical therapy. He thinks that the clergy have a most important responsibility in this matter and fears that many of them will indulge in a most unfortunate dabbling with disease. They will assume control of cases they have no business to touch. If," says he, "a minister was really anxious to ameliorate the suffering of humanity, I could educate him in a week. I should like him to spend that week in a large children's hospital and live among the little crippled bodies and wizened yellow faces of those innocents slain from their birth, who shall never come out of tribulation, for they are destined to bear the burden of all the sins and ignorance and greed of our society. There let the minister ask and answer his questions as to the actuality of disease."

Ischochymia.—By this term F. H. Murdoch refers to a condition characterized by the constant presence of food in the stomach in the fasting state. It may be either acute or chronic. The acute form is often called acute dilatation of the stomach and is due either to a paralysis of the gastric muscles, to a pyloric spasm, or to both. It may follow a gross dietetic error and occasionally follow chloroform anesthesia. Of 64 recorded cases, 47 proved fatal, 29 of these following chloroform anesthesia. The chronic form may follow mechanical pyloric obstruction or weakness of the gastric expulsive forces. Detailed enumeration of the causes acting under these various headings are given. Two degrees of the affection are distinguished. If food taken at night is found in the stomach the next morning, it is considered to represent a high degree of ischochymia; if food persists seven hours after ingestion, a low degree. In regard to treatment, the author quotes Hutchinson as follows: Operation is never justifiable as soon as the diagnosis of congenital pyloric stenosis has been made. One can never be sure that medical treatment is going to fail until the condition of the child is already so bad that the chance of recovery after operation is almost *nil*. He believes with Bloch, that the stenosis in these cases is the result of spasm which leads to a secondary hypertrophy of the pylorus, and that this hypertrophy disappears as the spasm passes off. Miller and Wilcox likewise believe that the medical treatment yields the best results, and are of the opinion that those children who die under medical treatment die with diarrhea, because the intestine has become too atrophic to deal with the food which passes into it when the pyloric spasm has been relaxed. Two cases are reported showing what may be done by medical means for the relief of benign pyloric stenosis in adults. In one case the stenosis followed the healing of a chronic gastric ulcer. Treatment consisted of rest in bed, liquid food, principally buttermilk, and silver nitrate in pill form. No cause could be assigned in the second case. Liquid diet and lavage effected a cure in this instance. The author observes that there is no doubt that gastroenterostomy would be the ideal treatment for all cases of benign stenosis of the pylorus if it were entirely free from danger, but so long as even a small percentage of patients die as a result of this operation it is the duty of the physician to employ every available means for the patient's relief before advising surgical intervention.

The Explosion of the Theory of Heredity.—A. Lapthorn Smith notes that while the idea of heredity in tuberculosis has undergone in the mind of the public a wonderful and beneficent change, the views along this line as regards cancer and insanity have remained almost where they were one or two centuries ago. In regard to the increase of cancer, the author says that he believes it due to the terrible mistake of regarding it as hereditary and unpreventable, whereas it is highly contagious. He finds it quite the exception to find anything hereditary about it. He believes it to be due to an ameba which gains access to the system through either the alimentary canal or some abrasion. It may circulate in the blood for indefinite time and finally find lodgment on some weakened area. To attack this enemy nature causes a cell proliferation in the vicinity and this proliferation becomes hard, due to a calcareous secretion from the ameba itself. We have considered as the disease itself, the manifestation which nature makes to stop the disease. This cell mass may gradually crumble before the assaults of the enemy and begin to ulcerate. Because cancer is considered hereditary and not contagious, no means are taken to stamp it out. It is therefore on the increase, while tuberculosis is on the decrease. In the beginning it is an absolutely local disease and should be removed at the earliest possible moment after its presence is suspected. A similar line of reasoning is followed with reference to insanity. The development of the latter affection is largely a matter of environment and habits of life. It is not logical to say that a malady is hereditary simply because it happened to a parent as well as to a child. The same *laissez faire* plan has been followed with reference to insanity as to cancer. The same idea holds true as to drunkenness. This also has been considerd as hereditary, but the author is convinced that it is simply a matter of inanition. He says he knows of several families where the father was a confirmed drunkard long before the children were born, and yet not one of those children care for alcohol; in fact, they loathe it. These children were for the most part educated away from home. In another family, where the father only took to drink after all the children were born, the five boys were brought up with the constant example of a drinking father before them, and four out of the five have become drunkards. If drunkenness was recognized as contagious instead of hereditary many a family might be saved from this disease, either by isolating the drunken father or by sending the children away when practicable.

Journal of the American Medical Association, September 19, 1908.

Genital Tuberculosis.—A. Martin, who says that, while the primary occurrence of genital tuberculosis from sexual contagion is possible and is to be considered, yet in the great majority of cases it is secondary to tuberculosis elsewhere in the body. It is not easy to estimate its frequency by specimens or autopsies, but he is convinced that thorough examinations would show it to be astonishingly common. The clinical diagnosis is usually difficult on account of the characteristic slightness of the symptoms. Tuberculosis of other organs, heredity, and contact with other tuberculous subjects are important in the diagnosis, and Martin attributes considerable value to the von Pirquet test, especially in pregnancy cases. A positive reaction, as shown by E. Martin, indicates that the patient has still the power to produce antibodies, so pregnancy may be allowed to continue. A negative reaction proves the deep injury that has been inflicted on the defensive powers of the organism, and interruption of the pregnancy is indicated. It is to be hoped that A. Martin's researches will be confirmed by the investigations of others. Ulcers of the external parts are suspected to be tuberculous when their sloughing surfaces are indurated, where undermined borders resist local treatment, and when testing shows they are not syphilitic. The microscopic determination in such cases is often difficult, many slides being needed to reveal the bacillus. The peritoneum shows two kinds of reaction, exudative and sloughing, giving rise to the development of hard masses of considerable size. It is impossible to say why the reaction takes one form at one time and the

other at another. This tuberculous peritonitis, especially the exudative form, is astonishingly frequent in young girls who rarely show in the beginning any localization in any other organ. The sloughing form was seen by Martin in one-third of his cases, and one-fifth of these were complicated by local infection of the adnexa. Two-thirds were of the exudative form, and one-half of these showed local infection of the genitals. The clinical diagnosis of peritoneal tuberculosis can be made in many cases with relative certainty. Ascites is always suspicious in the absence of neoplasms and diseases of the heart, liver, and kidneys, particularly in young women. The dry or sloughing form of peritonitis gives rise to hard masses simulating neoplasms or inflammatory infection. In most cases these show an abnormal location, not connected with the organ. The history and the localization of tuberculosis elsewhere, etc., will aid the diagnosis. The prognosis in all these cases is grave. There is always the chance of a latent localization elsewhere than where we see it. As to treatment, Martin confines his considerations to local and surgical measures. Ulcers of the vulva and vagina and of the endometrium can easily be removed. In the latter he prefers the application of strong astringents after curetting. Cases complicated with gonorrheal or septic infection need special care; in these he does not advise immediate operation, but waits till urgent indications call for it. When operation is indicated he prefers to remove only those parts so thoroughly diseased that healing seems impossible. Radical operations can not be considered here, as the possibility of hidden tuberculosis elsewhere can not be excluded. If possible, he operates by the vaginal route. Ascites he treats by free abdominal incision, by which he can reach its localization as a rule, occasionally only by the vaginal route. The removal of large nodules and sloughing masses, especially when connected with the intestines, seems to be useless from his experience. Conservative operations were done when indicated, and generally with good results. Especial attention was given to the after-treatment, the family physician, friends, and in case of poor patients some charity organization interested in the case were all instructed in the modern methods of phthisico-therapeutics. In some cases much benefit was observed from the use of guaiacol and creosote preparations. In none of his cases did the operation prove unfavorable in itself, as in no case was it performed except under urgent indication. Of 27 patients observed for over a year after operation, 16 were well and 6 have been considerably improved. Lumbar anesthesia was found well adapted to the cases. In all the cases the bacillus was present; if other cases in which tuberculosis was not so definitely diagnosed were included, the results would be still more favorable.

Symptomless Fibroid.—T. B. Eastman calls attention to the possible dangers from fibroid tumors of the uterus which may give rise to no symptoms and may be unsuspected before being revealed by operation, or in some cases even only by microscopical examination. It is generally conceded that there is an etiological connection between fibroma and cancer of the uterus, and Eastman quotes authorities on this. The alleged rarity of uterine sarcoma is, he says, more apparent than real; the proportion of cases of sarcomatous degeneration is increasing because they are being found out. There is little force in the argument that such tumors are not really degenerations, but were sarcomata from the beginning. Necrotic degeneration, which, according to Tracy's statistics, occurs in nearly 5 per cent., is the most dangerous one with which we have to deal. Including carcinomatous, sarcomatous, necrotic, and myxomatous degenerations, we have 12.1 per cent. of fibroids that ought for safety to be removed, and which in most cases might pass unsuspected by the examiner. The teaching, that it is well to advise patients with symptomless fibroids to temporize as regards operation is therefore bad—the radical advice to have them removed is much better for the patient. The mortality of 6 per cent. in the hands of competent operators is a less risk than the 12 to 14 per cent. of threatened degenerations which will be fatal if neglected, and in which a later operation will be much more serious.

Typhoid Carriers.—W. H. Park gives the results of investigations made at the Research Laboratory of the New York City Board of Health. These include the history of a cook who carried and spread the disease nearly everywhere she was employed, and who still after sixteen months' isolation and unavailing treatment with internal antiseptics, etc., is discharging the bacilli in great numbers. Examinations were also made of convalescents from the disease in two State insane hospitals and typhoid germs were found in the stools of 6 per cent. These results show that the same conditions exist in this country as in Europe, namely, that fully 2 per cent. of persons who have had typhoid fever are typhoid bacilli carriers. But besides these there are many who have become infected without developing the disease, and Park estimates their number as probably one in every five hundred adults. As most typhoid cases occur before the age of thirty, the average life of typhoid carriers must be about twenty-five years, so that we have the appalling fact that there are at least half as many recovered typhoid cases carrying bacilli as there are typhoid cases in any year, let alone the number of carriers who have never themselves had the disease. Park thinks that isolation is therefore out of the question except in special cases, like the cook mentioned, and that we shall have to rely on the more general methods of preventing infection and safeguarding our water and food supplies, not only when typhoid abounds, but at all times, as we now know that in every community unsuspected typhoid carriers may exist.

Hemorrhoid Operations.—J. D. Singley points out the danger in the ligature method of treating piles from possible infection of veins, he having observed one case of fatal pyemia, and a number of cases of embolism following this apparently simple operation by capable and clean surgeons. There is certainly a definite though low mortality that should cause it to be discarded in favor of better methods. The Whitehead operation is most satisfactory from the operator's point of view, but it may cause simple or infection embolism, and there is a risk of stricture and of incontinence which should outweigh its operative attractiveness. The clamp and cautery method, in his opinion, is free from these objections if properly performed. The hemorrhoidal masses should all be caught and brought down before any of them are cauterized, the clamp should be applied in the long axis of the bowel to avoid annular stricture, and it is better to burn away the clamped hemorrhoids instead of cutting them off before cauterizing, to avoid possible hemorrhage and infection. While less attractive as a surgical procedure, the freedom from the objections stated above, he thinks, should make it the operation of choice in almost every case.

Ranula.—T. L. Gilmer says that he formerly held the opinion that ranula was due to obstructions in Wharton's duct or the ducts of Rivini, but having found no cases of ranula on the floor of the mouth which prevented the passage of a probe through the whole length of Wharton's duct, and not having seen a case in which the sublingual or submaxillary gland enlarged or became painful, he has come to the belief that the usually held theory is wrong. Other observations showing obstruction or stenosis of the ducts without interruption of the flow of saliva have strengthened this opinion. Chronic inflammation resulting in enlargement and hardening of the glands is the most common disease, with the exception of epidemic infectious parotitis, and is most common in the submaxillary gland, but may occur in the others. It comes on slowly and is not painful, therefore the physician is not often consulted until some disfigurement results, and he reports a case in which a calculus seemed to be the originating cause. His observations lead him to believe that ranula is most often due to either cystic degeneration of parts of the sublingual gland separated from the main portion, cysts originating in the gland itself, or cysts originating in the mucous glands in the floor of the mouth. Calculi in the salivary glands are, he thinks, merely incident to diseased conditions already existing. He has never found them except in Wharton's duct. The disease described by Mikulicz is mentioned. It is manifested by symmetrical swelling of the salivary or lacrymal glands, or both. Its etiology is obscure. Other conditions noticed in the paper are tuberculosis of the sublingual gland and diverticulum of Steno's duct, cases of which are reported.

Blood Pressure.—J. Eichberg holds that test of blood pressure should form a part of the routine examination of each case, account being taken of both systolic and diastolic pressures. The Recklinghausen tonometer provides for both and is in other respects a satisfactory instrument. Examinations should be made under different conditions in the same patient before estimating the blood pressure as an element of diagnosis, and they should not be too prolonged. Variations in amplitude, or the difference between systolic and diastolic pressure, in the same individual constitute a very important part of the study. It increases in organic disease of the kidney, arteriosclerosis and aortic insufficiency, and diminishes for other organic diseases of the heart, affecting the valves or myocardium. In a healthy circulation it increases with moderate exercise, but every deficiency of the circulation shows itself in a reduced amplitude, even if the systolic pressure is increased. Systolic values of over 130 mm. call for further study. The most important feature of the study of blood pressure is found in its behavior under tests with varied amounts of measured work. Eichberg reviews the various conditions that influence blood pressure, pointing out especially the important influence of the nervous system.

It is in chronic conditions that the study is of the greatest value for diagnosis and treatment. Mere high or low pressure determinations are of little use; hypertension of itself is not a disease and may be conservative, as in chronic kidney disease, calling for no interference, but a pressure that is at all times above normal may be the only and often the earliest evidence of arteriosclerosis. The question of whether the high tension is injurious depends largely on the condition of the heart and its adaptability to the work required. If it still has a certain training capacity, compensatory hypertension is not needed.

The Lancet, September 12, 1908.

Two Cases of Gallstone Ileus; Operation; Recovery.—The patients of G. P. Newbolt were women of 54 and 58 years, respectively. The stones weighed when dry 303 grains and 280 grains. They were removed by longitudinal incisions in the gut. The main point of interest, says the author, was the type of bowel obstruction present. Though the symptoms were in both cases acute in onset and lasted some days, neither patient looked as ill as might be expected and the soft though distended abdomen with absence of tenderness on pressure was most marked. Both women were too stout to allow palpation either before or during anesthesia to give any information. Neither gave any history suggestive of malignant disease, and rectal examination during anesthesia was negative. Nor did the history of either case reveal any previous experience with gallstones.

The Action of Two Sera Upon a Carcinoma Occurring in Mice.—Experiments were made by C. E. Walker with the injection of a testis serum and a tumor serum, the full details of which are laid down. The conclusions reached are suggested by the following statements: (1) In 743 mice not treated with either of these two sera the tumors in two have dried up and dropped off spontaneously. (2) In a batch of ten mice treated with testis serum obtained 14 days after last injection of rat, the tumors in seven became suddenly gangrenous. In one the tumor dried up and came away. (3) In a batch of ten mice treated with tumor serum obtained 14 days after last injection of rat, the tumors in seven dried up and came away as small scabs. (4) In mice treated with testis or tumor serum taken from rats killed eight days after the last injection, the tumors became markedly hyperemic. This did not occur in mice treated with normal rat serum. They also grew more rapidly than the tumors in mice treated with normal serum. (5) In mice treated with testis or tumor serum taken from rats killed 14 days after the last injection, tumors grew at much less than half the rate of the tumors in mice treated with normal rat serum. If these facts are not due to a remarkable series of coincidences, it would seem that the prolonged injection of the living cells of the testis of the mouse into rats, produces in the blood of the rats a body which has a selective action upon the cells of the particular tumor dealt with in these experiments and upon those cells of the testis that are out of co-ordination. It would seem probable also that this body would have a similar action upon any cells out of co-ordination with the rest of the body and therefore upon other malignant tumors occurring in mice. The same seems likely to be the case with the blood of the rats treated with the injections of the living cells of this particular tumor, except that there would probably be a selective action upon this particular tumor only and not upon any others.

Fatal Toxemia after Chloroform Anesthesia.—M. F. Taylor's patient was a male child of two years and nine months, admitted to hospital for operation on an inguinal hernia. He appeared perfectly well and his previous history was negative. Chloroform was given with occasional small quantities of ether on the open mask. The course of the anesthesia was normal and its duration twenty minutes. Twenty-four hours later the child showed marked symptoms of collapse. The usual remedies gave no result. In thirty hours the temperature began to rise and the patient became very restless. In thirty-eight hours after operation he became comatose and died in that state. The case closely resembles those already reported both in symptoms and pathological findings. In two ways, however, it appears to differ. First, in the evidence of hyperplasia of the lymphatic tissues to the extent indicated; secondly, in the appearance of the blood, a bright cherry-red color being very apparent in the lungs and over the skin area rendered hyperemic by friction during preparation for operation. The first condition leads one to consider the possibility of a moderate degree of lymphatism acting as a predisposing factor in cases of delayed chloroform poisoning. The second condition leads to the suggestion of the possibility of chemical alteration of the blood, leading to the fatty changes observed in the organs. There has been great stress laid on the finding of acetone, diacetic acid, and β-oxybutyric acid in the urine. The condition is often described as an "acid intoxication." The "acidosis" is by no means a constant feature and when it occurs it is more likely to be a symptom of the condition than a cause. If acetone is derived from fat or if from proteid, there is sufficient excess of the former or disintegration of the latter as certified post-mortem to account for the appearance of β-oxybutyric acid or its derivatives in the urine in these cases. There is an intoxication but it remains qualified.

Deutsche medizinische Wochenschrift, September 3, 1908.

Pyocyanase in Throat Affections.—Saar has used this preparation as a spray in diphtheritic sore throat, in Vincent's angina, and in sore throat of scarlet fever. Every case was diagnosed by bacteriological examination. Previous laboratory experiments showed that the preparation had a solving effect upon the diphtheritic membrane, partly inhibited the growth of diphtheria bacilli in cultures, but did not bind the toxin of that disease. Clinically, the spraying with pyocyanase led to rapid diminution in the extent of diphtheritic membranes; the sore throat of scarlet fever, accompanied by streptococci, was quickly relieved; Vincent's angina was controlled in two or three days by the spray; simple sore throat with exudation upon the pharyngeal and tonsillar mucous membranes was likewise very favorably affected by the new preparation. Pyocyanase cannot take the place of diphtheria antitoxin, but may enable the use of smaller doses of it than usual. It has a distinct bactericidal action, but does not seem to possess antitoxic properties.

Effect of X-Rays Upon the Testicles.—Herxheimer and Hoffmann have studied this question by experiments on rabbits. They conclude that the most differentiated cells, that is, the spermatozoa, are the first to be injured by the rays; later the various cells out of which the spermatozoa develop are affected. The basal cells of Sertoli, on the other hand, begin to increase in number and with the greatly proliferated interstitial cells fill up the seminal canals. After a certain time a few remaining partly differentiated cells begin to regenerate the seminal elements, which process is much more complete than has been assumed from previous experiments. Spermatozoa are certainly produced in such regeneration, and this observation is of great practical value in the light it throws upon the possible outcome of similar x-ray injuries in human beings.

French and Italian Journals.

Elephantiasis Nostras of the Female Genital Organs.—R. Traina and E. Marconi base their observations of elephantiasis on a case observed by them in the person of a little girl of 6 years who had enlargement of the genital organs beginning in her third year. The growth removed was carefully examined microscopically. There were no enlarged or altered glands, and no history of syphilis, congenital or acquired. The authors consider especially the etiology of this affection. It has been attributed to syphilis, trauma, erysipelatous inflammations, blenorrhagia, and altered lymphatics and blood-vessels. The author believes that we are not justified in saying that syphilis is always its cause because in many cases there is no history and no other evidence of syphilis, and while syphilis is frequent elephantiasis is comparatively infrequent. Neither inflammations, obstructions of the lymphatics, nor of the blood-vessels alone are competent to cause the condition, and in the temperate climates the filaria sanguinis hominis is not found. The authors conclude from the examination of their case and their study of the literature of the affection that it arises from a number of causes combined at the same time. It generally occurs between the ages of 20 and 40 years, and pregnancy causes the growth to enlarge rapidly.—*Annali di Obstetricia e Ginecologia,* April, 1908.

Erysipelas in the New-Born.—A. Herrgott describes erysipelas in the new-born infant as a very serious and generally fatal disease. The fatality depends on the absence of reaction against the germs, due to the absence of phagocytosis in the new-born child. After the age of three months the prognosis is quite otherwise because here phagocytosis goes on normally. Starting from the solution of continuity at the umbilicus the germs enter the tissues and are not opposed by the lymphatic glands. They enter the lymphatics of the subcutaneous tissues, where they are found in great numbers, as also in the outer coats of the blood-vessels. A rapidly fatal peritonitis closes the scene. The external redness and swelling are slight, the symptoms of peritonitis being the first seen. Treatment has no effect.—*Annales de Gynecologie et d'Obstetrique,* May, 1908.

Special Article.

IMPERIAL INSTITUTE FOR THE STUDY OF INFECTIOUS DISEASES, TOKYO, JAPAN.

By S. MATSUI,

TOKYO.

LIBRARIAN OF THE INSTITUTE.

History.—In the year 1890 Prof. Kitasato returned to Japan, being honored with the title of professor by the German Government, after he had spent five years of study in that country and made himself known among the scientists of the day. The people of Japan received him indifferently.

FIG. 1.—Prof. Dr. S. Kitasato, Director of the Institute.

There were, however, more delicate minds, perceiving at once the true merit of the professor and of bacteriology. The late Mr. Fukuzawa, one of the greatest educators of new Japan, and the late Mr. Nagayo, president of the Japanese Private Hygienic Association, rendered Prof. Kitasato substantial assistance. The foundation of the Institute was there laid in the form of a private institution consisting of a few laboratories in a building given by Mr. Fukuzawa, situated at Shiba Park, Tokyo. Meanwhile Mr. Hasegawa introduced a bill in the Imperial Diet providing for a yearly grant of 15,000 yen for three years, and it was passed. At the expiration of the term specified for the annual appropriation a new grant was made to cover another three years. In the year 1899 the Institute was made a government institution.

The Institute then consisted of three departments, with a director, three department chiefs, and some twenty assistants. During this period its work chiefly consisted of the study of infectious diseases in general, their causative agents, and the means of their prevention. Besides, a course of lectures in bacteriology thrice a year, each covering three months, was given to physicians and veterinarians. It, however, again underwent a change in the year 1905.

Prior to this time the government of Japan had established a serum institute and a lymph farm, each separately. But it was thought more convenient in the way of administration to unite the three under one Institute for the Study of Infectious Diseases. This was effected by a bill passing the Diet in 1904, and the present Institute was completed in the year 1906.

Organization.—By the provisions of Imperial Order No. 88, 1905, the enlarged Institute was organized, and its work set down by the Minister of the Home Department in a proclamation issued the same year. The order and instruction are partly as follows:

Imperial Order No. 88—The organization of the Institute for the Study of Infectious Diseases shall be as follows:

1. The said Institute belongs to the Home Department and transacts the following work: Investigation of the causative agents of infectious diseases; study of prophylactic and curative means; examination of prophylactic, disinfecting, and curative methods; technical instruction of medical men in the study of infectious diseases, and preparation of vaccine lymph, sera, and other bacteriological, prophylactic, and curative materials.

2. The said Institute shall have the following offi-

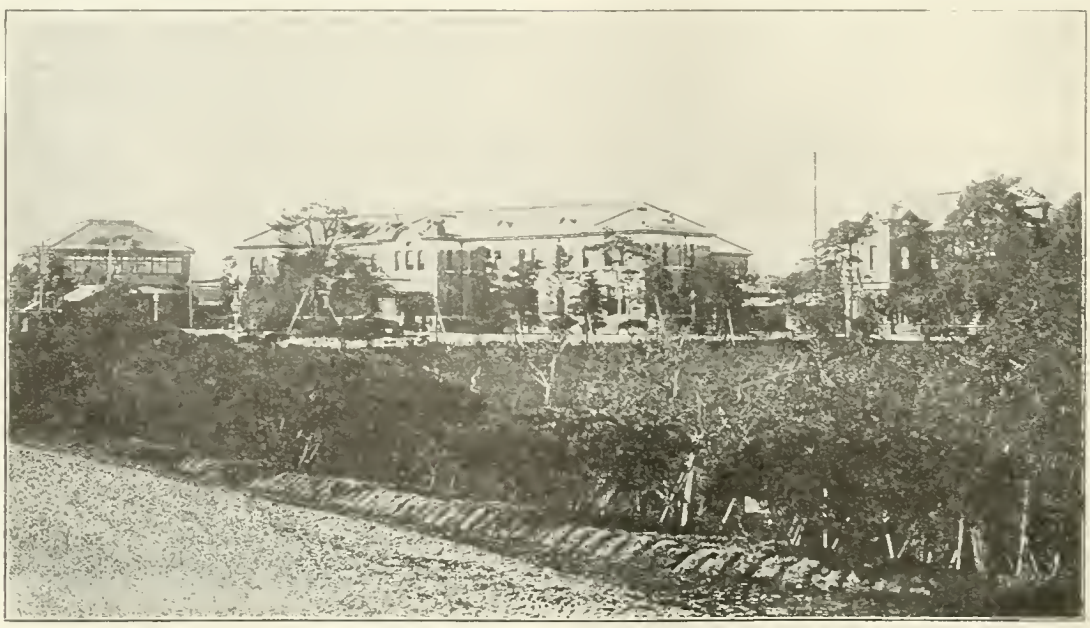

FIG. 2.—General View of the Institute

cials: a director, seven experts, twenty-three assistants, and seven clerks. It may have less than twenty assistants without pay.

3. The director is an official of "chokunin" grade (*i.e.*, an official who is nominated by the Emperor). He is under the direction of the Minister

Fig. 3.—Corridor of the First Main Building.

of the Home Department, and shall have charge of the administration of the Institute and superintend the subordinates.

4. The experts are guided by the director and participate in the work of investigation, examination, instruction, and preparation.

5. The assistants are directed by their superior officials and carry out the work of investigation, examination, instruction, and preparation.

6. The clerks are directed by their superior officials and shall attend to the clerical work.

In order to carry on the work of the Institute under Prof. S. Kitasato, it is divided into the following six departments:

1st Department. All kind of work regarding the investigation of the cause of infectious diseases and their prophylactic methods is done in this department. This department is further divided into three laboratories, *i.e.* the bacteriological, the protozoological, and the chemical. The department chief is Prof. T. Kitashima, who is also the chief of the bacteriological laboratory. Chief of the protozoological laboratory is Prof. M. Miyajima, and that of the chemical is Dr. Y. Teruuchi.

2d Department. All kind of work relating to the treatment of patients with infectious and other diseases is done in this department. To this department are annexed laboratories, a hospital, and medical offices for patients. Prof. G. Shibayama is chief of this department.

3d Department. Examination of disinfecting, curative, and prophylactic preparations for infectious and other diseases, and instruction of medical men in bacteriology and epidemiology are the work of this department, of which Dr. S. Hata is chief.

4th Department. Preparation of sera and other bacteriological, prophylactic, and curative products is made in this department. Prof. K. Shiga is chief of this department.

5th Department. Preparation of vaccine lymph is made in this department. Veterinarian S. Umeno is chief of this department.

6th Department. The sale of lymph, sera, and other preparations and clerical work are attended to in this department, of which Mr. T. Yoshizawa is chief.

There are nineteen assistants working in the departments and laboratories. Six clerks belong to the sixth department, with nine employees. Besides these, there are about seventeen non-commissioned members belonging to one or other of the departments.

Description of the Building.—As we stated above, the new enlarged Institute requiring a spacious building in order to carry on its whole work, the government allowed a sum of 300,000 yen for erecting the new Institute. A hill situated at the southwest extremity of the city, by the name of Shirokane, was chosen for its site. The whole compound, covering an area of 100 acres, constitutes a most charming spot for this kind of work. More than seventy large and small buildings are scattered over the compound. The brick house and the wooden one of two stories standing together in the middle of the grounds are called the first and the second main building. To the left of the second main building and close by is the pest laboratory building, and to the left of it and facing the first main building is the administration building, of two stories. To the back of this building are the hospital and the nurses' dormitory, each one story. To the back of the second main building are a shed for the preparation of culture media, the engine house, and the disinfection building. A stable for small animals stands to the left of the culture media building and at the back of the pest laboratory. Back of this stable is the photographer's building. In front of this building is the lymph preparing building.

A short distance apart from these are nine stables, eight of which are built parallel to each other. They have complete compartments for about 200

Fig. 4.—Students' Laboratory.

horses, which is the average number the Institute has for the purpose of preparing sera. They face a number of stores, employees' dormitories, the blood collecting building, all of which stand in one row with a drive between them and the stables.

Three stables for calves (having compartments for eighty-four calves) and an employees' dormitory, a veterinary dissecting building together with the building for the preparation of lymph, make another row standing parallel to the last-mentioned dormitories and stores.

At the northeast corner of the compound are an

Fig. 5.—Interior of the Research Laboratory.

isolating stable for cattle and the autopsy building. At the north corner is a veterinarian's residence. At the southeast corner, on another hill, separated from the main grounds by a natural vale making a pond, are a recreation ground, the dining-room, five official residences, and a kitchen. On this side of the hill is the main gate, whence a drive of about 200 yards leads to the main building of the Institute.

Equipment and Arrangement.—Let us come back to the first main building to examine what sort of equipment and arrangement are provided for each laboratory in order to make a complete investigation and study in this branch of science which we call the study of infectious diseases. This building contains six laboratories of experts, the private office of each adjoining his laboratory. Along the entire available window front of each room is a microscope table, 30 inches above the floor and 25 inches wide, and each room has three windows, so that three persons may have their seats

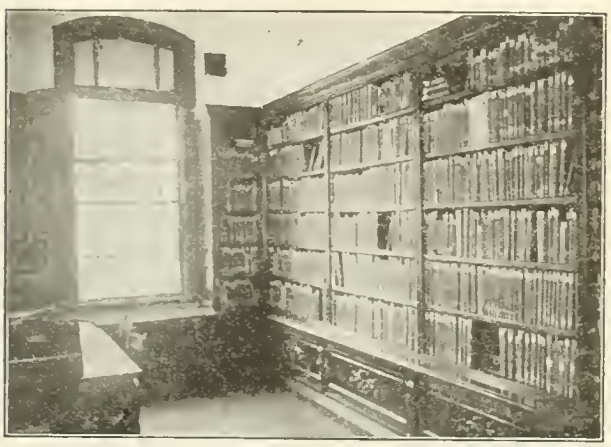

Fig. 6.—A Corner of the Library.

in a room. Beside each window, at a convenient point, is a gas bracket. Each table has closets and drawers. In the center of each room is a large double work desk supplied with gas and water, with a large sink and drip board at one end. The desks are 35 inches high, and are intended for the general work of the laboratory, providing facilities for heating, filtering, distilling, etc. On these tables and desks are arranged the apparatuses, such as microscopes, sterilizers, microtomes, surgical instruments, glass utensils of every kind, stains, chemicals, tissue fixers, etc. Besides, each room is provided with an incubator and some cages for the

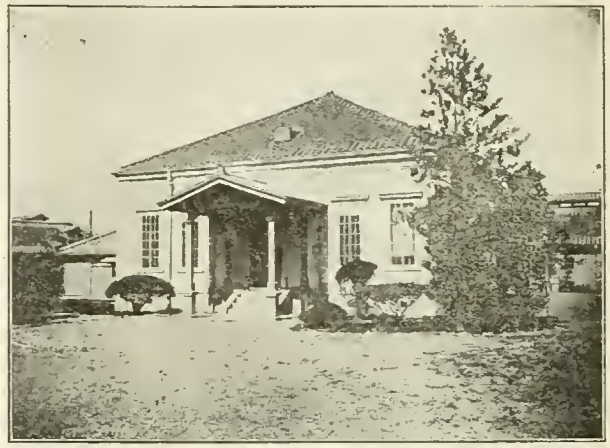

Fig. 7.—The Plague Laboratory.

feeding of animals, such as rats, mice, etc., under examination. Indeed, the number of apparatuses, both large and small, is very large and ample. Enumeration of them would exhaust the space allotted to this article. These are the chief and general equipments which each room in the first main building has.

The library is at the left corner of the first floor, occupying two rooms, one of which is used as a reading room and the other is filled with book racks; it is of fireproof construction. It contains over 3,000 volumes and 1,500 pamphlets, written in English, German, French, Italian, Spanish, Russian, Danish, etc. But most of them are German and English books. Besides, there are about 1,500 Japanese books and periodicals. With the exception of about 300, all of these are medical and bacteriological works.

The specimen exhibition room is at the left corner, just above the library. It is divided into two rooms and has six large showcases. In these cases

Fig. 8.—Entrance to the Hospital.

are arranged various kinds of specimens of sera, lymph, toxins, and other bacteriological products, both domestic and foreign. Here are also exhibited pathological and anatomical specimens.

Let us now pass on to the second main building, which may be reached by a long covered hallway.

The first floor of the right wing is mostly occupied by the chemical laboratories. A narrow hall runs through the middle of the building. To the right of the hall are three rooms, the library (branch room), an apparatus storage room, and a weighing room. To the left are a dark room for spectrum

Fig. 9.—Serum Collecting Room.

analysis and a furnace room. At the end of the hall is a large chemical laboratory. It is rectangular in shape. Along both short sides, which have windows, are two microscope tables, and in the middle is a broad work desk. To the wall just opposite to the door leading to the hall is attached a hood, which will supply facilities for work with such materials as should be excluded from the general laboratory air. Along this room, and quite apart from the main building, is built a small room with another hood over the furnace; here is done such work as would cause an offensive smell, or even give rise to poisonous gases. The chemical laboratory is well equipped with every kind of apparatus and chemicals which are necessary to carry out the work of the most advanced science of biochemistry, as well as chemistry in general.

To the left are three rooms for assistants and a refrigerator room. To the left of the large room, and separated from the main building, is an incubator room. It is supplied with a large incubator, 9 feet in height and 6 feet in width, with a gas boiler which supplies steam to the incubator. In this room is a microscope table, which is supplied with gas and water. These rooms are used for preparing various kinds of toxins.

The second floor of this building is again divided into two wings by the hall in the middle. The right wing has three laboratories along the hall and an expert's private room. These rooms have also the same equipment and arrangements as the other laboratories, and are used for preparing materials for Pasteur inoculation. Pathological and anatomical examinations (but not dissections) are made in one of these rooms.

The left wing has the same number and arrangement of rooms as the right. These are used entirely for the study of veterinary medicine and surgery, especially for the examination of lymph prepared at the lymph farm.

The culture media room is provided with autoclaves and sterilizers. All sorts of culture media are prepared in this room. The stable for small animals, such as rabbits, guinea pigs, monkeys, cats, dogs, and the like, is provided with about 100 cages, each containing two or three animals.

The pest laboratory building has two laboratory rooms, one culture media room, one animal room, one sterilizing room. These are all in one building with special device for rat exclusion, and all windows and other openings are covered with wire screens, in order to protect the rooms from insects.

The engine room equipment consists of a Westinghouse 29-horsepower gasoline engine, directly connected to a Westinghouse 17-kilowatt generator, besides a vacuum pump, several electric motors connected with a storage battery, a 6-horsepower gasoline engine connected with a large centrifugal apparatus and a vacuum pump by means of belts. Adjoining this room is the boiler room. It is equipped with a 5-horsepower boiler connected with a water pump and an autoclave, in which all infected clothing, bedclothes, and the like, used in the hospital are disinfected. The boiler also supplies hot water for the baths.

The photographer's room is divided into two parts, one apparatus room and the other the dark room. Its equipment consists of a great photomicrographic apparatus of Zeiss, an ultramicroscope, an ultraviolet-microscope, etc., together with a switchboard and other necessary electrical apparatus.

The lecture course building consists of two large rooms, with some smaller compartments for a culture media room, a dining room, a waiting room, etc. The work room occupies the whole area upstairs, four walls of which are covered with glass sliding doors, so as to furnish as much room for microscopic examination as possible. There are seats for seventy persons. The largest room downstairs is the lecture hall, which is constructed so as to be darkened when it is necessary to use lantern slides during the lectures.

The hospital equipment consists of two physicians' offices, two pavilions, the kitchen, the dining room, the nurses' dormitory, the meeting room, the bath, the autopsy room, and the wash room. The first physicians' office is further divided into two consulting offices, the physicians' room, the dispensary, the meeting room, the resident physician's room, etc. The second physicians' office is divided into disinfecting room, two consulting offices, the examination room, the dark room, the apparatus room, the meeting room, etc. The first pavilion consists of the operating room, seven wards, with

Fig. 10.—Interior of the Animal House.

accommodation for fifteen patients, provided with the latest equipment. The second pavilion is divided into eight wards, with twenty-five beds. The ground under the floor of the sick ward is covered with concrete, and the floor is double, so that the room may always be kept dry as well as warm.

All the windows are provided with wire screens to keep away insects and other intruders.

Present Work of the Institute.—Bacteriology, or we may more properly say the study of infectious diseases in general, was of very limited scope ten years ago, but it has gradually increased its field, and nowadays a bacteriologist must have a complete outfit of microscopes, chemical laboratories, stables in which various kinds of animals are kept, with an ample knowledge of medicine, zoology, botany, chemistry, etc. We have, therefore, not only medical men, but also zoologists, veterinarians, and chemists among our staff. Manifold as the work is, it may be divided into two great parts for convenience sake. One is the official which is required by the regulation, and the other, more individual in character, which is freely granted to every member of the Institute.

The official work consists of preparation of sera, lymph, prophylactic fluids or vaccines, examination of disinfectants, pathological material, and the like for the public, and the instruction of medical practitioners in bacteriology.

The sera supplied by the Institute for the public are as follows: antidiphtheria serum, in liquid and dried form; antitetanus serum, also in two forms; antityphoid serum, antidysentery serum, anticholera serum, antipest serum, antistreptcoccus serum, antivenom of "Habu," a venomous snake inhabiting the Loo Choo Islands. These sera are highly efficacious, and especially those of diphtheria and dysentery. Here is pepared an antidiphtheria serum, one cubic centimeter of which contains 2,000 immunization units, which is said to be very rarely prepared in any laboratory, and we owe it to Prof. Kitashima and to the technique of Dr. Hida, who has in charge the preparation of the serum. Prof. Shiga has succeeded in preparing a polyvalent antidysentery serum which is highly prized for its efficacy by medical practitioners.

The vaccine lymph is prepared after the method Mr. Umeno has introduced. His method is to prepare lymph exclusively of animal origin never passing through the human body, and it is highly efficacious. Its yearly preparation reaches the enormous amount of more than 1,700,000 tubes, one tube containing a sufficient dose for five persons, and therefore we can safely affirm that over 8,000,000 persons receive vaccination with the lymph of our make each year out of 50,000,000 of the Japanese population.

The prophylactic fluids or vaccines prepared in the Institute are those of pest, typhus, dysentery, and cholera. These are used whenever those epidemics break out.

Besides these the Institute supplies tuberculin and erysipelas antitoxin. All these biological products, viz., sera, vaccines, tuberculin, and erysipelas antitoxin are sold to physicians and druggists at home and abroad.

The examinations of disinfectants and pathological material is made from time to time at the public request.

The instruction of medical men is given thrice a year, each term lasting three months, to which physicians and veterinarians are admitted.

The most valuable achievements, in the light of science, which have hitherto been accomplished in the Institute, are the discovery of the dysentery bacillus by Prof. Shiga, experiments on treatment with various kinds of sera, prophylaxis by means of preventive vaccines, the therapy of erysipelas, the prophylaxis of hydrophobia, and works on the immunization theory.

Book Reviews.

Handbook of Medicine and Therapeutics. By Alexander Wheeler, L.R.C.P. and S.E., and William R. Jack, B.Sc., M.D., F.F.P.S.G.; Assistant to the Professor of Practice of Medicine, Glasgow University; Assistant Physician to the Western Infirmary of Glasgow. Third Edition. New York: William Wood & Co., 1908.

The object of this little volume is to enable the student to digest the main features of the various diseases in the most concise manner at the time he is engaged in clinical work, thereby enabling him to verify at the bedside the statements he has read; and to enable the busy practitioner to see at a glance the principal points of each disease, which he can elaborate by his experience. Though of small size, the volume is much more than a mere compend. The diseases of the special organs are prefaced by a brief summary of the anatomy and function of those organs in health; and the physical signs of the various diseases are not only described, but as far as possible their production is explained. The book is well arranged, and the material presented is calculated to be of benefit to the student and practitioner.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia. Assisted by H. R. M. Landis, M.D., Assistant Physician to the Out-Patient Medical Department of the Jefferson Medical College Hospital. June 1, 1908. Philadelphia and New York: Lea & Febiger.

The current number of Progressive Medicine contains articles on: (1) Hernia, by W. B. Coley; (2) Surgery of the Abdomen exclusive of hernia, by E. M. Foote; (3) Gynecology, by J. G. Clark; (4) Diseases of the blood, diathetic and metabolic diseases, diseases of the spleen, thyroid gland and lymphatic system, by A. Stengel; and (5) Ophthalmology, by E. Jackson. The Contribution on Gynecology contains a most important and timely section of forty pages on cancer of the uterus, and the subject of cancer in general is incidentally discussed. Progressive Medicine is too well known to need more than a mere mention of the appearance of the June number.

The Treatment of Gonorrhea in the Male. By Charles Leedham-Green, M.B., F.R.C.S., Surgeon to the Queen's Hospital, Birmingham; Surgeon to the Birmingham and Midland Hospital for Children; Consulting Surgeon to the Birmingham General Dispensary. Second Edition. New York: William Wood & Company, 1908.

The fact that a second edition of this book became necessary in less than two and a half years of the first issue, demonstrates its acceptability. This edition is certainly written up to date, including, as it does, a description of Goldschmidt's irrigating urethroscope and the use of Bier's hyperemic treatment in gonorrheal arthritis. It is singular that so careful an author as Leedham-Green should have omitted the fact that George Walker of Baltimore published the details of an urethroscope like the one mentioned at the same time that Goldschmidt presented that described. The author accepts a misapprehension regarding the employment of the Valentine irrigator, in that he implies that in order to obtain varying pressures it is necessary to elevate the irrigator to varying heights. The fact is that the receiver of the irrigator is kept at the same elevation throughout and the varying pressures needed are obtained by a simple stop-cock. Aside from such minor oversights, the book certainly supplies the demand for a brief, concise work to serve as an introductory to the study of this important disease. The author's manner of handling his subject justifies the hope that a larger, more exhaustive work may in the near future be expected from his pen.

Bradycardia and Tachycardia. Part II, in a Series of Monographs on the Symptomatology and Diagnosis of Disorders of Respiration and Circulation. By Prof. Edmund von Neusser, Professor of the Second Medical Clinic, Vienna; Associated Editor of Nothnagel's Practice of Medicine. Authorized English translation by Andrew MacFarlane, M.D., Professor of Medical Jurisprudence and Physical Diagnosis, Albany Medical College. New York: E. B. Treat & Co., 1908.

This small volume contains the translation of the two lectures by Professor Neusser on bradycardia and tachycardia, long well known to such medical men as read German. Dr. MacFarlane has put the German text into very readable English and Dr. Malcolm Douglas has supplied the appendix containing short abstracts of English and American articles, as well as a foreign bibliography of the subjects considered by Neusser.

Physical Signs of Diseases of the Thorax and Abdomen. By James E. H. Sawyer, M.A., M.D. (Oxon.); M.R.C.P. (Lond.); Casualty Assistant Physician and Medical Registrar, the General Hospital, and Physician to Out-Patients, the Children's Hospital, Birmingham. New York: William Wood & Co., 1908.

This book is intended for medical students, and will serve as an introduction to the study of physical diagnosis. There are two introductory chapters on the general condition of the patient, and the topographical anatomy of the thorax and abdomen. Then follow chapters on the physical examination of the thorax and abdomen, with explanation of the signs as ascertained by inspection, palpation, mensuration, succussion, percussion and auscultation. The volume contains numerous illustrations, and a few tables of differential diagnosis.

The Student's Handbook of Gynecology. By George Ernest Herman, M.B. (Lond.), F.R.C.P., F.R.C.S.; Consulting Obstetric Physician to the London Hospital, Consulting Physician-Accoucheur to the Royal Maternity Charity and to the Lower Hamlets Dispensary, Late President of the Obstetrical Society of London and of the Hunterian Society, etc. With 170 illustrations. New York: William Wood & Co., 1908.

This is a condensed edition of the author's larger and well-known work on the Diseases of Women. All explanatory, argumentative and speculative matter has been omitted, as well as references to rare cases and descriptions of operations not commonly performed. No space is devoted to instruction on anatomy, anesthetics or antisepsis, as the student is supposed to obtain the necessary information on these points from other sources. The present volume will prove of great value to students in the wards and dispensaries; it is the size of an ordinary compend, with the contents of a first-class textbook, and is written by a recognized authority. It has all the good qualities of the larger work, is only a quarter of the size, and half the cost.

Cancer, Relief of Pain and Possible Cure. By Skene Keith, M.B., F.R.C.S. (Edin.); Author of "Introduction to the Treatment of Disease by Galvanism," "Electricity in the Treatment of Uterine Tumors," "Gynecological Operation," and George E. Keith, M.B., C.M., Author of "Text-Book of Abdominal Surgery," with Mr. Skene Keith. New York: The Macmillan Company, 1908.

This is the description of the treatment of malignant disease, carcinoma and sarcoma, by means of an injection of a solution of iodipin, arsenate of iron, cacodylate of iron, and cinnimate of sodium. The modest claim of the authors is well expressed in the title. They do not assert that they have found a cure for the disease, but only that an experience of five years has convinced them that the method will often afford marked relief, assuaging the pain and apparently prolonging life, and in a few most favorable cases even seeming to cause a disappearance of the neoplasm. Although having little hope in the curative power of the knife, the surgical method is still strong enough to lead them to advise operation in every case when possible, following it with the injections. In very early cases, however, where a delay of three or four weeks would not imperil the success of a subsequent operation, they advise a resort to the injections first and an indefinite postponement of surgical treatment so long as improvement continues. The book is well worth a careful reading by all who believe that cancer can ever be cured definitely only, if at all, by medicinal means, and that surgery at the best affords but a chance of permanent relief.

Health at Its Best v. Cancer. By Robert Bell, M.D., F.F.P.S., Formerly Senior Physician to the Glasgow Hospital for Women; Author of "Cancer; Its Causation and Treatment Without Operation;" "The Cancer Problem in a Nutshell;" and "The Woman in Health and Sickness." London and Leipsic: T. Fisher Unwin, 1908.

In this book the author pleads for freedom of speech and open discussion of health topics, the suppression of which through motives of false modesty is responsible for the great amount of ignorance in sanitary matters which still prevails. As a rule the directions on health subjects given by Dr. Bell are in every way excellent, though he appears to have a leaning toward raw food faddism, that latest development of vegetarian extravagance. In the chapters treating of cancer the author expounds his well known views regarding the etiological action of autointoxication, and the curative effects of thyroid extract. The work is interesting, even to those who cannot accept all its teachings, and is provocative of thought, which is, after all, or should be, the chief aim of any book dealing with subjects not yet definitely settled, for it is the gaining of an audience and a hearing that is the most difficult work of the preacher of a new doctrine. If the message he has to give is true, it will prove itself if only attention can be drawn to it. There is much outside evidence to lead to the plausibility of Dr. Bell's theory of the causation of cancer, and there is also some corroborative testimony regarding the value of thyroid extract in the treatment of the disease.

The Pathology of the Eye. (Awarded the Nettleship Gold Medal of the Ophthalmological Society of the United Kingdom.) By J. Herbert Parsons, B.S., D.SC. (Lond.), F.R.C.S. (Eng.), Assistant Ophthalmic Surgeon, University College Hospital; Assistant Surgeon, Royal London (Moorsfield) Ophthalmic Hospital; Ophthalmic Surgeon, Hospital for Sick Children, Great Ormond Street. Volume IV. General Pathology—Part II. New York: G. P. Putnam's Sons. London: Henry Frowde and Hodder & Stoughton, 1908.

The fourth volume of "The Pathology of the Eye," by Parsons, is devoted to the pathology of injuries to the eye and orbit, to the pathology of exophthalmos and enophthalmos, panophthalmitis, orbital cellulitis, embolism, sympathetic inflammation, symptomatic diseases of the eye, and to the influence of heredity on the eye, the whole under the heading "General Pathology." The plan of the work is similar to that of the preceding volumes. The text is not prolix, but is comprehensive and to the point. The bibliography is extensive. The illustrations, all of which are in the text, are as a rule excellent, faithfully depicting the conditions that they are intended to represent. The entire content of the work is valuable. The chapter on heredity is of particular interest, the effect of heredity on the various tissues of the eye being given in detail. Diagrammatic charts representing the transmission of the various conditions through generations, graphically depict the various conditions that have been detailed. The work of Parsons is truly monumental and is fully worthy of the high appreciation which has been accorded to it by ophthalmologists throughout the civilized world. It is a store of knowledge of the pathology of the eye from which the present and succeeding generations will derive great benefit. No ophthalmic surgeon can afford to be without it.

Movable Kidney. Its Pathology, Symptoms and Treatment. By Harold W. Wilson, M.B., and C. M. Hinds Howell, M.B. London: Edward Arnold, 1908.

An attempt has been made in this book to give a concise account of the various conditions included under the term movable kidney. The experimental work was done at St. Bartholomew's Hospital. While the little volume is carefully and attractively written, it does not appear that the authors bring anything new to the study of a subject well known to general surgeons. As a compilation of all that is best in the literature of the subject the assiduity of the authors deserves the commendation of all who have to do with this essentially surgical condition.

Studies from the Laboratory of Surgical Research, Department of Surgery, Columbia University.

The College of Physicians and Surgeons is doing very important work in the field of experimental surgery and in this first published volume of studies results more or less conclusive are arrived at. There are studies in intestinal exclusion, in antiperistalsis and upon the function of pylorus and stomach after gastroenterostomy. In addition to these Dr. J. W. Draper Maury has done some interesting work in "technical surgery," including his twine triangular stitch for gastro- and enteroenterostomy, and records his observations upon a form of exophthalmic goiter in a dog. The use of methylene blue as an aid in diagnosis of pyelonephritis is explained by Dr. Edwin Beer, and Dr. N. B. Leggett has written a report of his studies in rectal anesthesia carried out on animals in the laboratory, and upon patients in the operating rooms of Roosevelt Hospital.

Points of Practice in Maladies of the Heart. By James Sawyer, M.D., F.R.C.P., etc. Birmingham: Cornish Brothers, 1908.

This book consists of three lectures delivered at the Royal College of Physicians of London. The aim of the lecturer was evidently to interest rather than to instruct. The author thinks that "true valvular thrill always shows forth structural valvular disease." If we could cure worry we would be far toward the cure of many "valvular neurotisms." He does not believe that either the presence or absence of an increased pulmonary second sound, either of high or low degree, is of any value in a diagnosis between mitral stenosis and mitral insufficiency. In the matter of diagnosis of cardiac lesions he prefers a solid wooden stethoscope.

Society Reports.

SIXTH INTERNATIONAL CONGRESS ON TUBERCULOSIS.

Held in Washington, D. C., September 21 to October 12, 1908.

(Special Report to the MEDICAL RECORD.)

FIRST GENERAL SESSION.

Monday, September 28.

HON. GEORGE B. CORTELYOU, SECRETARY OF THE TREASURY, PRESIDING OFFICER, IN THE CHAIR.

THE Sixth Triennial International Congress on Tuberculosis was opened on Monday, September 28, at 11 A.M., in the National Museum by Secretary Cortelyou, who represented President Roosevelt. He said that he considered it a great honor to be called upon to preside over such a distinguished gathering and especially to do so as the representative of the President of the United States. He said that the President had sent his congratulations in the name of the American people upon the work that had already been accomplished and upon the promise of far greater accomplishments in the future. He assured the foreign delegates that our people appreciated not only the interest but the cordial spirit of good will which the governments had shown in sending their delegates. He said that we were living in an age not only of great material but of great moral movements. It was a time of widening vision, deepening research, and broadening cooperation. The time when the people sat idly by and left the study and investigation of evils which menaced the welfare of humanity to the desultory investigation of a few had passed away and we now had concerted action either under governmental inspiration or governmental encouragement. A very brief outline of the work done in this country in combating the ravages of tuberculosis would not be out of place. The first organized movement in the United States was begun by the Pennsylvania Society for the Prevention of Tuberculosis in 1892 under the leadership of Dr. Lawrence A. Flick. Since that time numerous other organizations had been formed, until we now had more than 200 such organizations in the United States. The National Association for the Study and Prevention of Tuberculosis and other similar societies were independent of governmental control, but the national government had prescribed rules to prevent the spread of the disease among its employees and had also established governmental sanatoria. The United States Public Health and Marine Hospital Service had established a sanatorium at Fort Stanton, N. M., on a governmental reservation of forty-five square miles and having an altitude of 6,251 feet. Here an average of 200 patients could be accommodated. The War Department had a sanatorium at Fort Bayard, N. M., and the Navy Department had a sanatorium in Colorado. The Agricultural Department was furnishing most valuable additions to our knowledge from time to time. Congress had made provision for a hospital in the District of Columbia for the treatment of indigent persons suffering with tuberculosis and also for an investigation as to the prevalence of tuberculosis among the Indians and the desirability of establishing sanatoria for them. A number of the States had provided for the creation of commissions for the purpose of making investigations as to the extent of tuberculosis in the various States and the best means for prevention and treatment. In a number of instances these investigations had led to the establishment of State sanatoria for the treatment of those afflicted with this disease. He referred to the First International Congress held in Berlin in 1899, which was the first to be held with governmental sanction. This congress and the Peace Congress at The Hague were the most notable events of that year, and of these the former was the most important since its efforts were directed against an ever-present enemy, while war was only an unfortunate incident in the history of a country. He spoke of the menace of tuberculosis from an economic and hygienic standpoint. In spite of the panics that had been caused by yellow fever there had not been as many deaths from this disease in 115 years as there were from tuberculosis last year in this country. It was estimated that there had been 100,000 deaths from yellow fever during this period, while there were 160,000 deaths from tuberculosis last year in the United States. The bubonic plague in India, since its outbreak in 1896, had not caused as many deaths in proportion to the population as had tuberculosis in this country during the same time. Tuberculosis had caused nearly three times as many deaths during the past four years in the United States as were occasioned directly as the result of the Civil War. The importance of such an international congress could hardly be overestimated. It had stimulated the crusade against tuberculosis in England, France, Germany, and Italy. In this country even the preparations for the congress had already exerted a wholesome effect in awakening interest and enlisting support in every State in the Union. In his letter to Dr. Flick, President Roosevelt had emphasized the good results of such an international meeting in the following words: "The International Congress of Tuberculosis is in the interest of universal peace. By joining in warfare against a common foe the peoples of the world were brought closer together and made to better realize the brotherhood of man." A similar idea by one of our leading reviews which said that this congress would be a peace congress since so many different nations with no thought of separate boundaries would join in making common plans against the most common and dangerous enemy of the people. This crusade against disease, unlike others in the past, was based upon exact knowledge and not upon empiricism, and he hoped that the results would mark a most notable advance in the crusade against this dread menace to national and international welfare.

The Hon. B. F. MACFARLAND, Health Commissioner of the District of Columbia, welcomed the delegates to the congress in behalf of the District. He said that although many international congresses were held here, none could exceed in importance the one which began on this occasion. In such a gathering as this nations, planning for the victories of peace, formed ties that were hard to break in order to war with one another. The executive government of the National Capital had just completed the newest municipal tuberculosis hospital and had secured municipal legislation for the registration of tuberculous cases and the free examination of sputum. It was endeavoring to improve and safeguard the milk supply, was eliminating the alley slums and cooperating with public-spirited citizens in the instruction of the people on the home treatment of the sick. The presence and counsel of the congress far outweighed the hospitality that they had to offer but not their desire to make their guests at home.

The remainder of the session was devoted to the responses of the foreign delegates, all of which expressed enthusiasm for the work and admiration for the achievements of the United States in combating tuberculosis. The speakers and the nations they represented were: Dr. Fermin Rodriguez, Jr., Argentina; Baron Hengelmüller von Hengervar, Austria; Prof. Denys, Belgium; Dr. F. Montizambert, Canada; Dr. L. Sierra, Chile; Dr. Jee, China; Dr. Juan J. Ulloa, Costa Rica; Dr. Joaquin L. Jacobsen, Cuba; Dr. Bernard Bang, Denmark; Dr. C. W. Richardson, Ecuador; Prof. Louis Landouzy, France; Dr. Arthur Newsholme, Great Britain; Dr. Lawrence Coromilas, Greece; Dr. Bengoechea, Guatemala; Dr. Josselin de Jong, Holland; Dr. Antonio Stella, Italy; Dr. Eduardo Liceaga, Mexico; Dr. F. Harbitz, Norway; Dr. Echeverria, Panama; Dr. Ladislaw Detre, Hungary; Dr. Sylvio Gurgeldo Amaral, Portugal; Dr. S. Trimescu, Roumania; Dr. A. Vladimiroff, Russia; Dr. Camilo Calleja, Spain; the Hon. Conrad Cedercrantz, Sweden; Dr. Fr. Egger, Switzerland; Dr. Luis Melean Lafinur, Uruguay, and others.

Prof. Robert Koch of Germany, who responded to the welcome for Germany, said that the tuberculosis situation in Germany had been distinctly favorable during the past three decades, the rate of mortality having been reduced one-half, which was equivalent to a gain of 30,000 lives per annum. They were still active in trying to diminish this decrease. Many sanatoria had been established in which 40,000 patients per year were cared for. Germany watched the work of the congress with the keenest interest. The enactment of laws for the housing of the masses were contemplated. The Robert Koch "Stiftung" had been created for the purpose of studying tuberculosis in all its aspects, and in order to find new ways and means of successfully combating tuberculosis. The work of this institution was not confined to Germany. He recommended it to the good will of all who desired to participate in the crusade against tuberculosis.

Dr. Edward L. Trudeau of Saranac Lake, N. Y., said that as a veteran who had been in the struggle against tuberculosis for 35 years no one could better appreciate the meaning of such a congress than he. He had struggled for long years against darkness and indifference. It gave him great satisfaction to see the reduction in mortality and the recoveries and to see the light flashing from nation to nation; all this meant much to science and to humanity and the end was not yet.

Secretary Courtelyou closed the meeting by thanking the delegates for all they had said in regard to the excellence of the work of this country in combating tuberculosis in behalf of the government and expressed the hope that much that would be of value would result from the meeting.

THE EXHIBITION.

This exhibit was the largest and most complete of its kind ever brought together in the history of the crusade against tuberculosis. It was of the greatest educational value, giving the most effective object lessons as to both the treatment and the prevention of the disease. There were exhibits from nearly every State in the Union, from the Army, the Navy, the Marine Hospital Service, institutions of learning, individuals, and societies. Many foreign countries were represented, and among them Germany, France, England, Switzerland, Sweden, Hungary, Russia, Belgium, Austria, Canada, Argentine, Brazil, Uraguay, and Japan contributed exhibits that bore witness to their interest in this crusade. The exhibit conveyed an idea of the extent and variety of work along both purely scientific and practical lines that could not have been presented so effectively in any other way.

Argentina.—The exhibit from this country, the work of the Argentine League against tuberculosis consisting of models of dispensaries, hospitals, municipal sanatoria, together with its educational propaganda, which won the first prize at the St. Louis exhibition in 1904, and two gold medals at international exhibitions in South America, was presented.

Austria contributed her literary work and a collection of fifty-two microscopical and pathological specimens.

Belgium exhibited 155 anatomical specimens, 250 photographs, plans for a hospital, a number of instruments, and the literature disseminated for educational purposes.

Brazil presented diagrams showing the mortality from tuberculosis compared with that from epidemics in the towns of Sao Paulo, Santos, and Campinas. Plans for a model dispensary and for popular sanatoria were exhibited.

Canada sent an excellent pathological exhibit from McGill University. The colors of these specimens were preserved by the method of Kayserling and most skilful mounting was displayed. The specimens demonstrated the lesions caused by the tubercle bacilli in every organ of the body. There was also a series of Petri, Pasteur, and watch-glass specimens, in all of which the colors were preserved.

France.—Dr. Paul Courmont and Professor Arloing of Lyons, presented a number of microscopic specimens and demonstrated lantern slides. Dr. Leon Petit, of Paris, exhibited illustrations of hospitals, educational pamphlets, and apparatus for purifying air.

Germany.—The exhibit had been arranged to present a clear picture of the state and success of the campaign against tuberculosis in the countries taking part in this congress. Most of the exhibitors had agreed to leave their exhibited objects in possession of the National Association for the Study and Prevention of Tuberculosis in Washington to be used for a permanent exhibition in Washington. The work had been carried on under the direction of the Central Committee for Combating Tuberculosis. It was this committee that organized the notable first "Congress for Combating Tuberculosis as a Public Disease." This committee advocated the establishment of information stations and stations for the care of pulmonic patients, which, since 1803, had been in existence in numerous cities in Germany and represented one of the principle factors in the list of measures for combating tuberculosis. Within the last year a number of forest recreating stations were erected. As the latest achievement among antituberculosis measures the forest school was described. Among the tuberculosis institutions in Germany were 99 public health stations with 10,539 beds, 36 private institutions, with 2,175 beds, so that 50,500 persons could be treated annually. Tuberculous children were cared for by 18 institutions, with 837 beds, and those threatened by tuberculosis by 73 institutions with 6,843 beds. One hundred information and providing stations were in operation. There were 82 forest recreating stations, 3 forest schools, 2 rural colonies, 13 invalid and nursing stations, 13 convalescent homes for tuberculous patients, and 18 special lupus stations. There was a graphic description concerning the general mortality and the mortality from tuberculosis. The tuberculosis mortality in Prussia for the year 1875 was 31.9 per ten thousand living persons. This proportion remained almost stationary during the following ten years, but a rapid retrogression of the mortality rate had been manifested since this time in consequence of the combative measures employed as the result of the discovery of the tubercle bacillus. In 1906 only 17.26 of every ten thousand living inhabitants died of tuberculosis. There were illustrations and plans of the healing stations, forest recreating stations, invalid homes, and children's recreating homes. Illustrations were furnished of plans for dwelling house for tuberculous workmen. These houses, isolated and situated near the forest in sunny locations, were either one or two stories high and were accordingly intended for one family or for six families. Each dwelling had one room entirely separated from the others. This separate room was especially large, heatable, well ventilated, with an adjoining veranda, and special water closet for the pulmonic patient. This granted the tuberculous person the greatest possible isolation without compelling him to live entirely separated from his family. For the purpose of obtaining the cheapest sick bed, the cheapest daily maintenance under the best conditions for therapeutic success, a new architectural style founded on the principle of increasing the surface of the building which came into contact with the free atmosphere, a system known as the "Terrace system" had been devised by which the front of each story was built behind the front wall of the story underneath. Besides better air penetration of such a terrace house, was the fact that all the rooms of the building were more exposed to the sun, and that on account of the slanting direction of the front, all rooms had the full benefit of longer daylight. The great advantage of this system was that from every window of every story one could enter at any time under open sky. This made it obvious that this system gave the possibility of bringing two valuable modes of treatment in full favor, the rest cures and the air baths. This new architectural style possessed the advantage of be-

ing quite fireproof and of making possible very attractive and picturesque buildings. The system was applicable especially for hospitals, but was quite desirable for hotels and living houses. The invalid insurance of the German Empire was a part of the imperial workingmen's insurance law, which aimed at protecting the workingman in their economical existence against the unavoidable danger and injuries of their vocation. This insurance system had been extended so as to provide help to tuberculous workingmen, and had proved to be of invaluable assistance in combating the disease.

Great Britain.—The pathological exhibit was especially notable for the fine technique displayed in the preparation of pathological specimens. There were exhibits from the pathological department of the Western Infirmary, Glasgow; from the Humphrey Museum of Cambridge University; from the University of Manchester, and that of Leeds; also from the University College of Bristol.

United States.—Many of the States had exhibits of institutions, sleeping tents, and all the paraphernalia for combating tuberculosis.

Federal Government.—The work of investigation of tuberculosis among the Indian tribes was of special interest. The census of the Indian tribes in June, 1907, was 68,919; the number of deaths from tuberculosis from this time until June, 1908, was 539; the proportion of deaths per 10,000 population was 78. Of these 34.3 per cent. were males above 16, 37.5 per cent. females above 16, 28.2 per cent. children under 16. Deaths from other than pulmonary forms of tuberculosis were 19 per 10,000 population. The work of the United States Public Health and Marine Hospital Service showed that the death rate per 100,000 was 173.5 for white men, 485.4 for the negro, and 506.8 for the Indian. Deaths from yellow fever in the United States since 1793 had been 100,000, while deaths from tuberculosis during the past year had numbered 160,000. Deaths from tuberculosis during the last four years were 640,000, while deaths from wounds in the Civil War during four years were 205,670. Comparing tuberculosis in the United States with the plague in India there were 23 deaths per 1,000 population from tuberculosis, while there were 19 per 1,000 from the plague in India during the past twelve years.

Pennsylvania, which was the first State to initiate organized work against tuberculosis, had a system of dispensaries for the free treatment of tuberculosis, one being located in each of the sixty-seven counties, embracing an area of over 46,000 square miles, and bringing the dispensary within the reach of 6,928,575 persons. It was from these dispensaries that the inmates of the State sanitaria were recruited.

New York.—The exhibit of this State received the attention of many. It was divided off into sections as follows: No. 1 showed where tuberculosis was bred. Here was to be found the permanent traveling tuberculosis exhibit of the Charity Organization Society of the City of New York, which was viewed by 150,000 people during a six weeks' stay at one place in New York City this year. No. 2 showed how tuberculosis spread. No. 3 showed the extent of the disease; over 10,260 people died of tuberculosis in New York City in 1907; 75,512 people died of tuberculosis in the United States in 1906. The records of the Health Department showed that there were 23,917 living cases of tuberculosis in New York City. No. 4 showed how tuberculosis was cured; also (a) how tuberculosis was discovered; (b) how tuberculosis was treated in the early stages; (c) how tuberculosis was treated in the late stages; (d) the home treatment of tuberculosis. No. 5 showed how tuberculosis was prevented. There were also exhibited many tuberculosis mottoes. Tuberculosis in New York City was largely a disease of the tenements, and there are still 300,000 dark rooms without a window of any kind, even to an adjoining room; this made the tuberculosis problem here unique. A model of interest was that of a block of existing tenement houses as it stood in 1900. This block, bounded by Chrystie, Forsyth, Canal, and Bayard Streets, then included 39 tenement houses, containing 605 different apartments, occupied by 2,781 persons, of whom 2,315 were over 5 years of age and 466 under 5 years. It contained 1,588 rooms, but only 264 water-closets and not one bath. Only 40 apartments were supplied with hot water. There were 441 dark rooms, having no ventilation to the outer air and no light or air except that derived from other rooms, and 635 rooms getting their sole light and air from dark and narrow airshafts. During five years there were recorded 32 cases of tuberculosis from this block, and during one year 13 cases of diphtheria. In addition during five years there were 665 different applications for charitable relief.

Bureau of Animal Industry.—This exhibit embraced many specimens of tuberculous lesions in various organs of animals used as food. One specimen of particular interest was that of tuberculous disease in guinea pigs which was the result of inoculation from the udder of a cow that had been inoculated with a tubercular culture of low virulence six years and four months before the material was obtained for use on the guinea pig. The inoculation did not cause a progressive tuberculosis in the cow, but the bacilli had lived and multiplied for more than six years and had produced fatal disease in the guinea pig. There were specimens of tuberculosis produced by inoculating guinea pigs with milk containing tubercle bacilli and specimens from hogs that had contracted the disease from eating feces of cows affected with tuberculosis. A group of interesting specimens demonstrated the action of light on the tubercle bacillus, showing that in dark places the tubercle bacillus retained its virulence thirty-two days or longer, while in electric light it died within thirty-two hours, and in direct sunlight it perished in one-half hour. Another interesting group of specimens showed how long the tubercle bacillus might live and retain its virulence in the ordinary salted butter. Tuberculosis had been caused by butter in which the bacillus remained alive after one hundred and thirteen days, after one hundred and thirty-three, and even after one hundred and sixty days. Another group of specimens demonstrated that the feces of tuberculous cows frequently contained the tubercle bacilli and that the introduction of such feces into the milk infected it with virulent bacilli, and that butter made from such milk also contained the bacilli. The amount of feces was very small, no more than usually found its way into the milk pail. It was shown that tuberculous cattle presented a better general appearance than most dairy cattle.

SECTION ON PATHOLOGY AND BACTERIOLOGY.

First Day—Monday, September 28.

THE PRESIDENT, DR. WILLIAM H. WELCH, IN THE CHAIR.

Address of the President.—Dr. WELCH, in declaring the first section of the Congress open, said it was his honor and privilege to extend a most cordial welcome to all in attendance upon this section and especially to the medical confrères from foreign countries. This section, he said, represented that aspect of tuberculosis work on which all intelligent and scientific activity must be founded. All measures must be based upon accurate knowledge of the spread of the disease and it was a matter of great gratification that there was present in the section Professor Koch, the discoverer of the organism, the greatest discovery made in this domain. Bacteriology and pathology must constitute the foundation of the campaign against the disease and he thought this section the fundamental one of the Congress. He expressed the hope that all in attendance would have an instructive, enjoyable, and profitable time.

Viability of the Tubercle Bacillus.—Dr. M. J. ROSENAU of the Marine Hospital Service presented this

paper. He said that practically all observers agree with Koch that human sputum is the chief source of infection. He considered the life of the tubercle bacillus outside the body and said that the belief that the tubercle bacillus contained a spore still lingers; that while there is absence of spores it contains a waxy substance which surrounds it as an envelope. The usual habitat of the bacillus protected it, but this protection was a question of environment, and not an inherent property of the bacillus. We possessed no satisfactory criteria of death and there was great difficulty in distinguishing between live and dead tubercle bacilli and between the lesions caused by the dead and the live bacilli. It was necessary to resort to secondary inoculations for this differentiation. In a series of eight guinea-pigs inoculated with the dead bacillus three died as a result. The discrepancy in experimental results was largely explained by failure to make secondary inoculations. The thermal death point was well established as 60 degrees C. for twenty minutes. The short life of cultures under most favorable conditions contrasted with the long life claimed for the bacilli under unfavorable conditions. The viability of the tubercle bacillus in sputum, soil, and water was discussed. In dry sputum it might live several weeks or months and therefore be a danger, but how great a danger was a question. When dried the great majority died quickly. The writer said that very little work had been done to determine the viability of the bacillus in water.

The Action of Diffused Light Upon Bacillus Tuberculosis.—Professor JOHN WEINZIRL of Seattle, Wash., said the action of direct sunlight upon bacteria had been the subject of numerous investigations; the results, however, were obtained by unsatisfactory methods and greatly minimized the effect of this important factor. By making direct exposures, *i.e.* without the intervention of media, etc., which absorbed the light, the writer had recently shown (*Journal of Infectious Diseases*, 1907, Sup. 3) that non-sporebearing bacteria, including tuberculosis, are killed by direct sunlight in a remarkably short time, generally between two and ten minutes. It appeared desirable to take advantage of the new method to test likewise the action of diffuse light upon bacteria and especially upon *B. tuberculosis*. Much had been written regarding the importance of light in dwellings, which must of necessity be largely diffuse light, but up to the present there was no satisfactory data on which to base conclusions regarding the action of diffuse light. The results of the present investigation indicated a considerable degree of variation in the powers of resistance shown by different species of bacteria. For example, *B. prodigiosus* was killed by diffuse light within a day, while controls kept in the dark lived five or six days. On the other hand, *Str. erysipelatos* showed strong endurance, five to nine days of continuous exposure being required to kill it; controls endured twelve days and might have lived even longer. Other bacteria tested presented intermediate degrees of resistance. *B. tuberculosis* was always killed within a week, and the shortest time was within twenty-four hours; controls grew for a longer time, but never after ten days. It was thought that desiccation would be the most serious disturbing factor and, hence, other controls were placed in moist chambers and exposed to diffuse light; almost invariably these controls were killed in a shorter time than the other cultures. The problem, therefore, becomes a very complex one, but it appeared certain that diffuse light materially shortens the life of the tubercle bacillus, the organism being killed within a week.

A Chamber in Which Dried Tubercle Bacilli May Be Handled Without Danger.—Dr. A. P. HITCHENS of Glenolden read this paper. The chamber was designed to avoid exposure of the operator during certain manipulations with dried bacteria, necessary for the preparation of the so-called new tuberculins. The chamber was 30 inches long, 24 inches deep, and 24 inches high over all. It had no bottom, but rested upon a very thick soft rubber gasket. It was made of heavy plate glass, the frame being brass. The lower half of the front, of reinforced tinned copper, could be removed. It was held in place by bolts and wing-nuts, accurate closure being obtained by the use of a rubber gasket. There were two openings, 8 inches in diameter, in this lower front. These openings had sealed into them rubber gauntlets long enough to permit the hands when inserted into them to reach all parts of the chamber. At one end of the chamber near the bottom was an oblong box, 8 inches long by 4 inches high by 4 inches deep. This was open on both sides, except for a fine wire screen at the inner side and a removable lid at the outside. The lid consisted merely of a frame and copper gauze. This box was packed with sterile absorbent cotton and served as an inlet and filter for air. The cotton was packed tightly enough to resist somewhat the entrance of air. At the other end of the chamber was a funnel 4 inches in diameter, tapering to about a half inch. This funnel was attached by means of rubber hose to a vacuum pump, but between the funnel and the pump itself there were two wash bottles, one containing bichloride solution, the other containing sulphuric acid. To use the chamber the lower half of the front was taken off and all the material and instruments to be used during the operation was put inside—in addition there was placed in a corner, out of the way, a dish of unslaked lime and a quantity of formaline-permanganate, or formaline magnesium sulphate mixture. It was the custom to throw a quantity of some antiseptic into the gloves so that if it should happen that there was a little opening in one of them there would be no danger of live germs getting upon the hands. The removable front was then put on and screwed down tightly; the vacuum pump was started—on account of the resistance offered to the entrance of air by the cotton filter, there was a slight negative pressure inside the chamber. If it should happen that there were any small cracks about the chamber, air would be drawn in at these openings, thus obviating any danger of the bacillary dust being forced out, when, for instance, the gloved arm was thrust suddenly into the chamber. After the work had been completed the product to be kept was sealed up. The formaline mixture was poured upon the lime and both the vacuum pump and the air filter-box were closed. Sufficient formaline was generated to destroy exposed living organisms within the chamber. The next morning the air filter was opened and the vacuum pump started, in order to remove the formaline before the chamber was opened. The advantages this chamber had over the usual devices for handling dried masses of virulent organisms were quite obvious. In some laboratories it was customary to use the ordinary hood with a current of air constantly carrying the powdered material away from the operator, but hoods did not always work, and if the old law "that what goes up must come down" applied to bacteria there would seem to be some danger to the immediate neighborhood from such a method. With this chamber the operator was absolutely protected and all the effluent was sterilized. The chamber might be used, not only for handling tubercle bacilli, but also for handling dried tuberculin, and other dangerous biological or chemical substances.

Dr. LILE of Cincinnati, discussing these papers, said that an important point brought out by the second paper was that the controls placed in moist chambers were killed in a shorter time than the others; if such was the case, our ideas of climatology in the treatment of the disease might not be rational. If humidity had a curative influence it should be dilated upon. He thought this phase of the subject should be gone more fully into.

Dr. WEINZIRL of Seattle, replying to this, said the experiments were not sufficient at the present time to establish such a principle. He thought that while dryness as such had nothing to do with the disease it did have an influence in changing temperature; in a dry atmosphere as

soon as the sun set it got cool and the patient got a good night's rest.

New Homogeneous Cultures of the Tubercle Bacillus.—Professor S. Arloing and Dr. Paul Courmont of Lyons, France, presented this paper. They considered this the most important question since it had been learned how to grow the bacillus. The method had been discovered in 1898 and had been confirmed by many observers. It consisted in the reduction of the bacillus in 5 per cent. glycerine bouillon; agitation made mechanically or by hand. By this method there was produced a culture that was homogeneous, that is to say, the individual bacilli were not gathered together; but lay separate in the culture. It resembled the culture of the colon bacillus; it was cloudy. Important changes were produced in the morphology; the bacillus was longer and finer, the length increasing with age of culture and there were bifurcations of the germs. In some were found streptococcic forms. The coloring properties were also changed. The acid-fast property was not present to a great degree. The virulence was greatly changed; it was diminished and injections into guinea-pigs were not particularly fatal; in the rabbit death might occur in days or weeks; in dogs there was great resistance and a powerful serum was therefore obtained. A serum was produced agglutinable by serum of tuberculous patients. The agglutination property might disappear after some months. This was not a rare culture, but the same cultures had been made in France by three or four investigators, and similar ones in Germany and in Philadelphia. It was not a particularly rare human bacillus form. Two of the cultures made were of the bovine bacillus.

Variation of the Tubercle Bacillus.—Professor S. Arloing, of Lyons, presented the work of twenty-two years in testing by inoculation and culture the varying degrees of virulence. He found that the guinea-pig was easier to inoculate than the rabbit. He classified the lesions according to degree of infectiousness. He found that in the surgical disease there was generally diminished virulence, as compared with the pulmonary tuberculosis, but that certain forms of bone infection equaled in virulence the pulmonary type. He had determined that there was a great variation in virulence from that easily cured to the greatest virulence. He explained the different results more upon the difference in virulence than upon any distinct race or type. He had carried out the same experiments with human and bovine bacilli and found the same degree of variation. By cultivating these different bacilli he had obtained all grades of virulence. He mentioned that in his first experiments made public in this line he found that he could change the type by producing a homogeneous culture and by increasing the temperature of the culture at different stages. By this method their properties were changed and the virulence diminished. He also found it possible to increase the virulence by subjecting the cultures to varying atmospheric pressures. As compared with human, the range of virulence was the same with bovine, but the degree of infection was greater with bovine. He concluded that it might be said that all tubercle germs were of one kind; that there were these variations, but they were not sufficient to form distinct types. He did not entirely agree with Dr. Koch in this respect.

Comparative Examinations Concerning the Practically Important Acid-fast Bacilli.—Drs. N. Jancso and A. Elfer, of Kolozsvar, Hungary, presented this paper, which was read by Dr. Detre. It presents the following conclusions: Cultures were made from 93 tuberculous patients, 11 bovines, 1 pig, and 18 chickens; for the greater part the inoculations were made directly on nutritive media and for futher study were employed 10 calves, 14 goats, more than 1,200 rabbits, more than 400 guinea-pigs, 300 chickens, 300 frogs, and 31 snakes. In relation to their main characteristics, morphology and pathogenesis, all of the cultures could be divided rather sharply into three groups; they corresponded to the typus humanus, bovinus, et aviarius. All the cultures cultivated from the 11 bovines were found to belong to the typus bovinus. The strains cultivated from the 18 chickens were all found to belong to the typus aviarius. The strain from the pig belonged to the typus bovinus. Among the strains cultivated from among the 93 tuberculous patients there was one with all the characteristic properties which under ordinary conditions were found only in strains living in other organisms, the typus aviarius. It might, therefore, be asserted that among the strains developed from the excreta of human beings there were also to be found some, which according to all their characteristic properties were the same living, acid-fast bacteria, as occurred under ordinary conditions in other animals—bovines, chickens; this was probably true, even though the authors were not able to isolate a single strain from among the 93 tuberculous patients (22 of whom were individuals younger than 14), which because of its characteristics of cultivation, as well as because of its pathogenicity toward rabbits and larger animals, could be counted among the bovine type. From comparative studies made by the authors with tubercle bacilli belonging to the same group, they were able to show that such organisms, even though belonging to absolutely one and the same group, might vary from each other in many of their characteristics. On the whole, most of the human strains produced but slight tuberculous changes in rabbits; several exceptions, however, had been found by the authors, in which the organisms produced a fatal termination in the rabbits; this fact the authors had demonstrated in this manner; they kept the animals which were being experimented on alive for some time and thus did not shorten the duration of vital activity of the bacilli. Organisms cultivated from different organs of one and the same individual showed marked variations from the standpoint of their most important characteristics. The investigations of the authors had shown how relatively easy it was to lessen the characteristics acquired by the different acid-fast groups in their present mode of life, and among these more particularly their specific pathogenicity; it was, therefore, to be assumed that the various acid-fast strains could be deprived entirely of their specific properties. However easy it might be, however, to lessen the degree of any of the easily recognized characteristics of individual acid-fast strains—and even to deprive them of these entirely—still it was extraordinarily difficult to convey to them new specific properties; no investigator had, in fact, ever succeeded in it in a manner satisfactory to the laws of natural science. As long as we did not have at our disposal certain incontrovertible transformation experiment performed and controlled with pure cultures, examinations with such terminal results as those of the authors would prove only that under the present modes of life the more important groups of acid-fast bacilli became more and more separated from each other in the realm of nature.

A Contribution to Our Knowledge of the Cultural Characteristics of Tubercle Bacillus.—Dr. Johan von Szaboky of Budapest-Gleichenberg presented this paper. The experiments of the author gave these results: (1) The luxuriance of growth of tubercle bacilli varied according to the nutritive medium employed. They throve best on lung-agar, next on sputum-agar and sputum-lung-agar, tuberculous lung-agar; not so well on egg media and somatose-agar. (2) The tubercle bacilli grew best and quickest on the very weak acid media, fairly on the slightly weak acid, neutral, and alkaline media, and not so well on the markedly acid media. Exceptions to this were somatose-agar and egg media. On the former they throve best and quickest when the agar was markedly alkaline, next when it was weakly alkaline, and worst when it was acid. When egg media were employed the best cultures were obtained when the reaction was markedly acid, next when it was markedly alkaline, and least when it was neutral. As in the greater number of cultures the rapidity of their de-

velopment corresponded with the luxuriance of the vegetation, accidental results must be considered excluded in these experiments. (3) The growth was constantly the best on media which were very moist, as lung-agar; worst on egg media, which possessed the least moisture. (4) It was to be supposed that the tubercle bacilli produced a change of the original reaction of the nutritive medium during their growth, as titration had demonstrated that the reaction of neutral media changed somewhat after the cultures had grown for several days. Such a change of reaction was noted in each series twice. In all the media which could be titrated, with the exception of the somatose-agar, the following change was noted: First, alkaline then acid, and finally again alkaline reaction was noted: in somatose-agar the reverse order was noted.

Second Day—Tuesday, September 29.

Routes of Infection in Tuberculosis.—Dr. J. Bartel of Vienna said that in animals we were able to demonstrate in the lymph glands, in addition to the manifest tuberculosis with specific tuberculous changes, a stage of "lymphoid" tuberculosis in which the glands showed mainly lymphocytic hyperplasia or were apparently "unchanged." The existence of such a lymphoid stage could be demonstrated in man also. Attempts at immunization, performed according to the observation of a possibility of a cure of the tuberculous infection in the lymphoid stage, gave in combination with reinfection the following results: Signs of increased tendency toward, then of increased resistance, and finally of complete immunity. Processes of complete cure in organs afflicted with manifest tuberculous changes. Mainly manifest tuberculosis of the lungs with the bronchial lymph glands and cavities in the lungs; but also isolated manifest tuberculous disease of the lungs, the portals of entrance remaining perfectly intact and all opportunity of direct lung infection being excluded. Under certain conditions, therefore, tuberculosis bore the character of a cryptogenetic infection. A similar condition must also be expected in the domain of human pathology according to the laws of natural immunity. Therefore, if only the signs of manifest tuberculosis were considered during a postmortem examination we did not have sufficient to act as a reliable basis upon which to judge the portal of entrance; the signs of lymphoid tuberculosis should also be considered. As far as could be judged at the present time infection from pharynx, stomach, and intestines was far more frequent, particularly during early life, than has generally been considered. It was difficult to judge the relative effects of deglutition and aspiration.

Sources and Ways of Infection of the Tuberculous Contagion.—Dr. G. Kuss of Angicourt, France, called to mind that the danger of infection by inspiration of dust was first proclaimed by Wielman, in 1879, and announced later by Koch. While Calmette and others insisted upon the importance of infection by the alimentary tract, he contended that the greater importance of infection by inhalation of dust must not be lost sight of. The writer undertook experiments to determine to what degree dust infected. Special devices were used in experiments, photographs of which were shown, the general line of experiment being to expose guinea pigs at various heights from the floor on which carpets had been beaten. It was found that infection was the more positive the nearer the guinea pigs were to the floor; the higher group being the safer. He considered that there was infection not only through the respiratory organs, but also through the digestive organs and pharynx. These experiments were also made with bacteria that were dried in the sun, and it was found that the ability of such bacteria to infect was lessened, showing the importance of sunlight in dwellings. He stated that it was important to note that it had been sufficient for a guinea pig to be exposed only once, and for only 20 minutes to this infection by dust to contract the disease.

Prof. A. Calmette of Lille in discussion, said that he had never wished to be understood as denying the possibility and frequency of infection by the pulmonary route, but what he insisted upon was that in chronic tuberculosis the alimentary tract was much the more usual route. He considered that there was a class of cases where infection by the respiratory route was evident, especially in young children, but outside of this period he thought that general infection was rare by that route when the respiratory apparatus was healthy. He thought the experiments of Dr. Kuss were not under normal conditions and might not be applied to human beings in that way.

Prof. K. Landouzy of Paris said that he shared the ideas of Dr. Calmette; he believed that infection by the respiratory route did not occur except through a lesion of the respiratory tract. It might occur in tracheotomized patients, for instance, the reason being that cicatricial tissue was established and phagocytosis interfered with. He referred to the prevalence of laryngeal tuberculosis, and said that in these cases there was often a history of syphilitic infection.

Channels of Entrance of Tuberculosis.—Dr. Samuel Bernheim of Paris quoted a great number of clinical facts and experiments on animals from which he concluded, contrary to the opinion of Professor Calmette, that tuberculosis was chiefly transmitted by aerial germs and by way of the respiratory tract. He thought the clinical data furnished by pathological anatomy and by experiments during half a century, instead of shaking the aërogenic doctrine of human tuberculosis, confirmed this conception of its etiology. That a great number of cases of tuberculous contagion by the dry bacilli of Koch incorporated in dry dust and numerous other objects, proved the virulence of this microbe even when not carried by a moist vehicle. The great facility of realizing in man, as well as in animals, an experimental tuberculosis by inhalation argued in favor of the view that the respiratory path was a common channel of infection. He considered the intestine as a door of entrance possible, but far from being the normal and usual one. The frequency of human tuberculosis in the countries where the use of milk and meat was very limited, the slight mortality of children by tuberculosis during the period of lactation, demonstrated, he thought, that the intestines played an altogether secondary rôle although an appreciable one, as a channel of entrance. The necessity of large doses of tuberculous products to produce an experimental tuberculosis and the numerous failures in obtaining it, he thought, did not argue in favor of the enterogenic doctrine. He believed bacillary heredity of tuberculosis did not exist; exceptionally the disease might result from hereditary contagion *in utero*, but could not be considered as an important factor in tuberculosis. He considered that the hereditary predisposition must be rejected, for infection in this way was in relation with the degree of contagiosity of the environment which produced phthisis and with the frequency of contaminations. The vascular path he considered to be rare as a channel of entrance and held that it was very difficult to demonstrate its importance. The genital tract must be considered as a factor of some importance in the propagation of the disease, as clinical observations and experiments demonstrated that this channel of entrance was far from being as rare as had been supposed. The anal orifice might also serve as a channel of entrance in the same conditions as the mucous membranes of the skin, and an important etiological rôle must be attributed to this region of the human body. The buccal mucous membrane in children must be considered as a possible door of entrance for cervical tuberculosis, and the skin might serve as a channel of entrance in conditions particularly favorable to contamination, but these could not be considered as factors of first importance.

Concerning Latent Tuberculosis.—Professor Francis Harbitz of Christiana said that some authorities con-

tended that the majority of cases of tuberculosis were due to infection in childhood or infancy; that it was now admitted that it was possible to demonstrate latent tuberculosis in the majority of individuals. At postmortem he had found evidences of tuberculosis in 70 per cent. This increased greatly in frequency with age; it could be much more frequently demonstrated in children than had been supposed; at post mortem it had been found in 42 per cent. The significance of latent tuberculosis in children was that the infection continued in the adult. In a series of cases he had been able to establish such latency after twenty and thirty years. He concluded that at present proofs were lacking to show that the majority of cases of tuberculosis in adults were due to infection in childhood, but that, considering the frequency of tuberculosis and evidence of its slow development, this must certainly be considered of great significance. As to whether infection in childhood produced increased susceptibility or a degree of immunity it was not at present possible to say.

The Predisposition of the Apices of the Lungs to Pulmonary Tuberculosis, Phthisis.—Dr. Carl Hart of Berlin said that, aside from infection, the cause of pulmonary tuberculosis in youthful individuals was to be sought in an individual predisposition due to anatomical and functional disturbance of the normal condition around the superior aperture of the thorax. These improper conditions might be congenital, hereditary or acquired during early life. The predisposition he considered at first purely local. Actual and functional diminution of the pulmonary apices not only favored the deposition of tubercle bacilli, but also diminished the natural powers of resistance inherent in the tissues. This predisposition determined the localization of the first tuberculous focus in the pulmonary apices. He considered that local predisposition was equally significant for air, blood and lymphatic infection. The final outcome of the battle between the tubercle bacilli and the tissues depended on the degree of this anatomical and functional disturbance in the region of the superior aperture of the thorax. Children did not exhibit this predisposition of the pulmonary apices to tuberculosis. In older individuals, those aged 50 or over, the predisposition was caused almost exclusively by inhibition of the function of the superior aperture of the thorax, due to senile changes. He concluded that the measures to be employed in combating tuberculosis should be directed, more than had been done in the past, against the development of an individual predisposition.

Dr. M. P. Ravenel of Madison, Wis., in discussion, expressed his absolute belief in everything Professor Calmette had said on the subject. He said it had been found that, in cattle with no pulmonary infection whatever, there was observed that condition of lymphoid infection spoken of by Dr. Bartel. It had been found that, on feeding dogs with the bacilli in an emulsion of butter, the germs could be obtained in the mesenteric glands within three and a half hours. He called attention to the work that had been done with swine by occluding the esophagus and feeding through a fistula in the stomach; with these animals they showed that the bacilli would pass from the stomach into the liver and lungs within twenty-two hours. He thought it unfair to say that these experiments did not apply to human beings It was well known that in cattle almost the first lesion was found in the retropharyngeal glands, which pointed to infection through the intestinal tract. Tuberculosis of swine, the speaker said, was increasing rapidly, yet no one claimed that they contracted the disease by respiration; the first infection was of the retropharyngeal glands.

Dr. W. H. Welch of Baltimore said, in reference to the infection of swine, there could be no question of its being of alimentary origin. It might be through the cervical glands, through the duodenum, or the mesenteric glands. But in swine we did not find the localization usual in human beings.

Tuberculosis of the Lungs and Asthenia Universalis.—Professor B. Stiller of Budapest presented this paper, in which he held that asthenia universalis was a widespread constitutional disease in the sense that it depends on hereditary tendency. Its attributes were enteroptosis, nervous dyspepsia, severe disturbance of nutrition without sufficient cause, atony of the stomach with flatulence, neurasthenia, and flacidity of the tissues. That the tendency showed itself in the atonic habit of the child; delicate skeleton; long, flat thorax; oblique ribs; small epigastric angle; and looseness of the costal girdle due to congenital defect of the tenth costal cartilage, which produced a floating tenth rib. That the phthisical habit was nothing else but the asthenic; this was its original meaning; the asthenic habit was the index of hereditary asthenic constitution, which also predisposed to phthisis. In nearly all consumptives who presented the phthisical habit there was found a floating tenth rib, and in a greater or less degree enteroptosis, nervous dyspepsia, neurasthenia, and the other attributes of asthenia. That in 70 to 90 per cent. of consumptives dyspepsia was nothing but enteroptosis or nervous dyspepsia. That the shortening and stiffening of the first costal cartilage doubtless increased the predisposition of the apices, but its etiological significance had been greatly overestimated as compared with the whole asthenic constitution. That the modern hygienic and dietetic treatment of tuberculosis in its true sense was a direct treatment of asthenia and not really of pulmonery tuberculosis.

SECTION ON CLINICAL STUDY AND THERAPY.

First Day—Monday, September 28.

Dr. Vincent Y. Bowditch of Boston, President, in the Chair.

Address of the President.—Dr. V. Y. Bowditch of Boston limited his address to a few words of greeting, and said that the session could not be comprehensive enough to include papers on all subjects, but had been limited to the consideration of only the newer methods of clinical study.

The Use of the X-Ray.—Dr. F. H. Williams of Boston read this paper. He first laid emphasis on the importance of protecting the patient so that the rays should reach him only at the point desired; and protecting the physician so that the rays should not reach him at all. This was done by putting the *x*-ray tube in a lead-lined box with an aperture sufficient to allow the rays to reach the desired area of the patient. The doctor was protected from even this beam of rays by examining the patient with a fluoroscope carrying a copper lead screen around it, and having the screen viewed through a section of lead glass. Then the quantity of light was cut down to the minimum efficient quantity. In skiagraphic work the doctor remained entirely behind a lead screen. In the fluoroscopic examinations records could be made either by the orthodiagraph or by tracings on the skin of the patient, the pencil being held in a long holder of metal, and then transferred from the skin to paper. In comparison with examination by auscultation and percussion, Dr. Williams considered the *x*-ray examination of greater value in showing more accurately the excursion of the diaphragm, the size, position, and displacement of the heart; in determining the condition of the central portions of the lungs (percussion, etc., showed only the surface conditions in the lung), and comparative densities of the lungs not only in different areas, but also in the same area on different days as shown by keeping records of the density as determined by a water densimometer used in connection with the fluoroscope. Dr. Williams said that the *x*-ray examination should not be used to take the place of auscultation, but only after

a thorough classical examination by inspection, palpation, percussion, and auscultation of the chest had been made, and the man that made the classical examination, if he were not experienced enough in fluoroscopy to make the examination himself, should at least direct it and aid in its interpretation to give the best results. As an aid in the early diagnosis of tuberculosis the value of the *x*-rays had been very great. Suspicious pictures had been obtained in cases with no cough, lung symptoms, or physical signs. In pneumothorax the diagnoses had frequently been made by the fluoroscope prior to the time when it was possible by the classical examination. In conditions simulating tuberculosis of the lungs the *x*-ray examination might be able to settle the diagnosis. Dr. Williams did not consider this method of examination infallible, but corroborative, more accurate, and sometimes earlier than the classical method.

Typhobacillosis.—Dr. L. Landouzy of Paris read a paper with this title. He said that the older classifications of tuberculosis recognized the caseous conditions and the miliary conditions, but that he had differentiated another type of bacillary septicemia, manifesting itself exclusively in a typhoid state with continuous fever, rapid pulse, and enlarged spleen, but without any visceral localization. Of great significance was the absence of rose spots. Typhobacillosis usually ended in recovery from the period characterized by the typhoid state, but later localized signs of tuberculosis appeared suddenly or insidiously, usually in the lungs, but frequently in the mesentery. In rare exceptions the continued fever terminated fatally in two to four weeks, and on autopsy nothing was found but the ordinary congestive and degenerative changes seen in all severe septicemias not limited to any one organ. The positive diagnosis during the typhoid period was made by the absence of the Widal and the presence of typhoid bacilli in stools, urine, or blood. The presence of the tubercle bacillus was proved by inoculation of the blood into the guinea pig, and by serum reactions. Moreover, the same pathological condition was produced by inoculations into animals of the tubercle bacillus. In closing, Dr. Landouzy called attention to the importance of the Widal reaction in the prognosis as well as the diagnosis of typhoid fevers, some of the cases of apparent typhoid in which the Widal was negative, being typhobacillosis with a very doubtful prognosis as to ultimate complete recovery, although recovery from the typhoid state was likely.

Mixed Infections.—Drs. M. P. Ravenel of Madison, Wis., and A. C. Klebs of Chicago presented this communication, which was based on the findings of a series of autopsies from which cultures were taken of the bacteria in the tissues, as well as in the tubercular cavities, and compared with the findings in animals of various species. The cavity formation was found associated constantly with streptococcus infection as well as the tubercle infection, and occurred principally in man and in monkeys. In cattle there was no cavity formation, but a frequent calcification. In cattle extensive mixed infections were almost unknown. In swine again there were no cavities, nor were the swine infected with the same organisms as were found in man. The animals seemed to have a different natural resistance to the strains of bacteria, some being immune to those that other animals were sensitive to. In the benefits of treatment by life in the country, Dr. Ravenel considered one of the most important factors to be the absence from exposure to influenza, pneumonia, colds, and the many secondary infections which abound in the city, and which in many cases are the direct and immediate causes of death.

Dr. S. Bernheim of Paris asked under what conditions the autopsy examinations were made, as the work of the French investigators had seemed to show that all the types of lesion and symptoms could be produced by the tubercle bacillus and its toxins.

Dr. Ravenel said that he recognized that the tubercle bacillus and its toxins had been shown capable of producing all these types of lesions, but from the fact that the tubercle bacilli were never found alone in the cavity cases and that streptococci were constantly found in and around these cavities, and that cavities could be produced by infecting a tuberculous animal with streptococci, he believed that these lesions were due to the mixed infection. He believed thoroughly in the teaching that the worst thing a tuberculous patient could do was to live in contact with a consumptive.

Duration of the Actively Infectious Stage of Tuberculosis.—Drs. R. N. Wilson and R. C. Rosenberger of Philadelphia read this paper, in which they considered congenital and acquired tuberculosis. In the congenital cases the infection from the mother was commonly granted as possibly of placental origin. The presence of congenital caseous pneumonias was well established also in the children of a healthy mother but a tuberculous father. Such tuberculous offspring had been begotten experimentally in animals from a healthy mother and diseased father. In a series of eight autopsies on men dying from tuberculosis the testicles and a couple of inches of the vas were removed and examined for tubercle bacilli, and in five of the fifteen specimens, even though the testes had all grossly appeared normal, positive smears were obtained. In the cases of acquired tuberculosis the secretions and excretions were examined, and routine examination of the sputum in cases in which there was no suspicion of tuberculosis at times showed the positive presence of tubercle bacilli. Moreover, in all cases in which the tubercle bacillus was found in the sputum it was found also in the feces, and in most cases in the urine. Inoculation into guinea pigs showed the tubercle bacillus present when it had not been found by tinctorial methods. In animal experimentation the feeding of tuberculous sputum was followed by the presence of tubercle bacilli in the feces on the third day and in the urine on the eighth day. The authors therefore considered that protection from the tuberculous patients had only just begun when all of the sputum was cared for, and that all the excreta should be disinfected for an indefinite time.

In response to a question Dr. Wilson said that the existence of the tubercle bacillus in a spermatozoon had not yet been demonstrated. The bacilli had been shown in the fluid in which the spermatozoa were suspended, but in animals it had been shown that injection of tubercle bacilli into the vagina immediately following coition of healthy animals would produce tuberculous offspring.

SECTION ON SURGERY AND ORTHOPEDICS.

First Day—Monday, September 28.

Dr. Charles H. Mayo of Rochester, Minn., President, in the Chair.

President's Address.—Dr. Mayo said that, notwithstanding the fact that tuberculosis affected practically every tissue in the body, the general public still regarded it as affecting only the lungs. It should be considered from the preventive, preservative, and constructive standpoints. Few diseases not self-limited tended so much to recovery as tuberculosis. The sources of infection should be studied. Stress should be laid upon the importance of infection from animals. Some patients reacted against the toxins of the disease, others did not. More and more the administration of medicines had yielded to the carrying out of various directions which were simply methods of correct living. Serum therapy had its place. Failures had enabled us to have better judgment in treatment. Hyperemia

was one of the recent methods of treatment. Publicity and the prevention of tuberculosis in animals should be given due consideration.

Tuberculosis of the Nose, Mouth, and Pharynx.—Dr. H. P. Mosher of Boston read this paper. He said that owing to the protective power of the nasal mucous membrane primary tuberculosis of the nose was rare. It was characterized by a superficial ulceration situated over the anterior part of the cartilaginous septum. Secondary tuberculosis of the nose was more common than the primary form. It was part of a general or of a pulmonary tuberculosis. The secondary form tended to produce tuberculous tumors. Nasal tuberculosis had a slow, painless and progressive course. As a rule it did not extend to the pharynx. In making a diagnosis of tuberculosis of the nose the chief disease to exclude was syphilis. Tuberculosis attacked the cartilaginous part of the septum, there was little if any inflammatory reaction, there was no odor, and its course was painless. Syphilis, on the other hand, attacked by preference the bone of the septum, and there were marked inflammatory reaction, odor, and pain. Tuberculous lesions were found in all parts of the mouth. The most common lesion was an ulceration. The first sign of a tuberculous lesion of the mucous membrane of the mouth was the appearance of a circumscribed area which was pale and slightly edematous. Within this there were small submucous yellow or gray tubercles. These soon broke down into a shallow ulcer. On cleaning the bed of the ulcer numerous tubercles were found scattered over it. The worm-eaten edge of the ulcer was set about with tubercles and granulations. Occasionally a tuberculous tumor or a tuberculous abscess of the tongue occurred, but the common lesion of the tongue was the common lesion of the rest of the month, namely, an ulceration. In most cases ulceration of the tongue, like other tuberculous ulcerations of the mouth, caused little if any pain; at times, however, ulcerations of the tongue were very painful. Trauma played an important part in causing and localizing tuberculous lesions of the mouth and tongue. The final and absolute test of tuberculosis of the nose, mouth, and pharynx was the finding of tubercle bacilli. Tubercle bacilli were hard to detect in tissue removed from the nose, mouth, or pharynx. The finding together of giant cells and caseation was very strong proof of tuberculosis. Before making a diagnosis of tuberculosis of the mouth, syphilis had to be ruled out. In certain cases where tuberculosis caused an abundant overgrowth of nodular tissue the presence of malignant disease was simulated. Tuberculosis of the pharynx was not uncommon as a secondary infection from tuberculosis of the lungs. Extensive tuberculosis of the pharynx was a serious complication because it interfered with the patient's swallowing. Such cases soon ended fatally. Tuberculosis of the tonsils often occurred secondary to tuberculosis of the lungs. In most instances it ran a mild course. Sometimes, however, the tonsils became deeply ulcerated like the rest of the pharynx. Primary tuberculosis of the faucial and the pharyngeal tonsil occurred in 5 per cent. of cases. The pharyngeal tonsil was infected by the air current, the faucial toncil by food. In what percentage of cases tonsillar tuberculosis was of the bovine type had not been determined. Wood maintained that 5 per cent. of children had latent primary tuberlosis of the tonsils. At any age there were few diseases which were latent in the body in such a large percentage of individuals. The tonsils were oftenest infected with tuberculosis in childhood during the time when the epithelium lining the crypts was spread apart and thinned by the passage of lymphocytes through it. While the germinal centers were active they showered lymphocytes into the surrounding tonsillar substance and upon the epithelium of the crypts. Tuberculosis of the tonsils rarely caused pulmonary tuberculosis or general tuberculosis. The great importance of tonsillar tuberculosis lay in the fact that an overwhelming majority of enlarged cervical glands were tuberculous and that these glands were infected from the tonsils. Cervical tuberculosis was limited to the glands of the neck; it seldom gave rise to tuberculosis of the apex of the pleura or the lungs. The first step in the treatment of enlarged cervical glands was to remove the tonsils by thorough dissection. The treatment of tuberculosis of the nose, mouth, and pharynx consisted in the thorough removal of the tuberculous tissue with the curette and the subsequent use of lactic acid. In this way small lesions might be made to heal for a time, but they broke down again. In small primary lesions of the nose, of the mouth, and of the pharynx the use of tuberculin would seem to have a special field.

Tuberculosis of the Larynx; the Type Which Is Capable of Recovery and the Principles of Treatment.—Dr. W. E. Casselberry of Chicago, who presented this paper, said he sought to establish for laryngeal tuberculosis that which was now realized with respect to the pulmonary affection—namely, the fact that certain persons developed a natural resistance sufficient to "arrest" the disease; and that many more offered a considerable resistance which might only just fail of the degree required for "arrest." It was shown (1) that tuberculous hyperplasia in the larynx could undergo resolution; (2) that unmistakable tuberculous ulcers did occasionally heal; (3) that favorable negative qualities which indicated a superior resistance and more hopeful outlook characterized in common the cases which had proven to be capable of recovery; and (4) that after a reasonable period of observation, these qualities persisting, it should be possible to differentiate the cases which were capable of recovery. The common conception of tuberculosis of the larynx was drawn from its harrowing course in about two-fifths of the cases—the unresisting type. Almost two-fifths composed a group in which the laryngeal complication ran a much slower but still fatal course. In one-fifth the lesions were in a state of arrest for a number of years. In the resistant type the three cardinal principles in the treatment of tuberculosis—rest, open-air life, and forced feeding—should be more rigorously enforced than in lung disease alone. Rest should consist not only in rest of the body and mind, but rest for the voice. Rest was of first importance. If it was important to immobilize a joint in the treatment of joint tuberculosis, it was just as necessary to put the larynx at as complete rest as possible in tuberculosis of that organ. As to fresh air, it should be fresh air, rather than any particular kind of fresh air. A locality should be selected where the patient could get local treatment when needed. The speaker laid special stress upon the recommendation that as soon as laryngeal tuberculosis was found to complicate pulmonary tuberculosis the treatment, not alone of the larynx, but of the disease as a whole, should be entrusted to one skilled in laryngeal technique.

Dr. Casselberry said, in discussing Dr. Mosher's paper, that a very practical point occurred to him in respect to tuberculosis of the tonsil—a point upon which he was asked to give a professional opinion more frequently than in any other phase of tuberculosis of the mouth. For instance, a child was brought with cervical adenitis and chronic hypertrophy of the tonsil. The lymphatic glands of the neck were enlarged and indurated. The duration might have been three weeks or three months. He was asked, "Are those glands tuberculous, and, if so, shall they be removed surgically?" In this connection he said he always re-

membered a series of several hundred cases examined at autopsy and after operation and reported from a hospital in Liverpool in which about three-fifths of the entire series were found to be tuberculous and the balance a simply pyogenic infection of the glands. We had no means of determining in the living child, especially where the condition had not been in existence for a great time, whether it was tuberculous or not. The speaker said that his universal opinion under these circumstances was that the enlarged tonsil, which had been the source of the infection, whether tuberculous or simply pyogenic, should be removed, wholly removed, with the capsule. The surgeon should then wait from three to six months. If the enlarged glands disappeared after the removal of the tonsils, then in all reasonable probability they were not tuberculous. If they had not disappeared, in all probability they were tuberculous, and should be removed surgically by external operation.

Dr. Mosher wished to emphasize the point brought out in Dr. Casselberry's paper, that there were two well-defined classes of cases of tuberculosis of the larynx, the hopeful cases and those that were not hopeful, and his warning to keep hands off in the nonhopeful cases.

The Construction of Hospitals for Tuberculous Patients.—Mr. Meyer J. Sturm of Chicago, in this paper, dealt particularly with the construction of hospitals for surgical tuberculosis. There should be sufficient air and sunlight, nourishing diet, facilities for securing tranquility of the mind and abundance of rest. These could be obtained in the ordinary manner except that special provision had to be made for the mechanism of supplying fresh air and a flood of sunlight. The location should be chosen so as to provide for an abundance of sunlight, absence of noise, absence of dust, absence of smoke, proper ventilation, disposition of sewage, safety from fire, possibility of future extension, and accessibility for patients, their friends, and the medical staff. Compactness could be secured by superimposed stories. It was important to have country branch hospitals, as undoubtedly many tuberculous patients did not go to a hospital because one was not easily accessible. They wished to be near their friends and relatives. It was also important to select a location with reference to its proximity to localities where tuberculous diseases prevailed. The speaker discussed in detail the location of the building on the ground, the shape of the building, balconies, porches, elevators and runways, the roof, rooms, wards, toilet and service rooms, diet kitchens, signal system for calling nurses, operating department, floors, wainscots, walls, etc.

Dr. F. Gallagher of El Paso, Texas, said that the plan of a hospital as presented by Mr. Sturm could scarcely be improved upon, even for a general tuberculosis hospital. He thought the speaker's intention was to bring out the value of a hospital for surgical tuberculosis alone. Dr. Gallagher thought it would be better, if possible, to have a separate hospital for surgical tuberculosis, and in such an event he knew of no arrangement which would more fully answer the requirements than the details presented by Mr. Sturm. Under present conditions cases of surgical tuberculosis had to be cared for either in institutions devoted to tuberculosis or in the surgical wards of our general hospitals. The hospital must be so constructed as to accommodate many patients under a single roof. The high cost of ground made the multiple story building necessary, and a building located too far from the center of business life would very largely preclude the attendance of physicians. And for the best results the attendance of doctors was necessary. There could be little doubt that the man in touch with the world of medicine outside the hospital would exercise the greatest influence for good in the hospital. Other things being equal, there could be no doubt as to the advantages of the open country sanatorium, situated away from the contaminating influences of the city where the air was largely germ-laden, and with other conditions which would permit living out of doors day and night.

Tuberculosis of the Cornea.—Dr. Oscar Dodd of Chicago read this paper. This was a rare condition, and presented a unique clinical picture, in that the lesions were of a transparent structure, allowing careful observation of their progress and the effect of treatment. It was nearly always secondary. The usual forerunner of the condition was a swelling at the corneal margin resembling phlyctenular conjunctivitis. This was composed of small foci of epithelioid and giant cells in which the tubercle bacilli were occasionally found. These foci gradually extended into the cornea, and with the general round-celled infiltration about them, gave rise to the typical clinical picture. Ordinary treatment had very little effect on these conditions, as they lasted for months, new foci occurring upon slight irritation. Tuberculin injections for diagnostic purposes caused a general and also a local reaction, which was manifested by marked inflammation of the eye, more infiltration into the cornea, and the formation of new foci. By the use of the new tuberculin (T. R.) in small doses, the spots would disappear, rarely leaving an opacity. Too large a dose of tuberculin was always followed by an increase of infiltration, taking several days to subside. This showed the care necessary in its use to prevent harm and bring about increased resistance to the progress of the disease.

Dr. F. H. Verhoeff of Boston thought that this subject should be considered from the standpoint of the tuberculosis rather than from the part of the eye involved. The ability to care for the tuberculosis was more important than the tissue involved. The condition might be either primary or secondary, but in an individual case it was almost impossible to say whether it was primary or secondary. It was extremely seldom that a case was met with that could be considered as primary. He recalled one case in which an injury of the eye was followed by a nodule in the iris. While this appeared to be a primary tuberculous nodule, yet he believed at the time that it was due to metastasis. The acute type was very rare, and went on to caseation and rapid destruction of the eye. The chronic type was characterized by a very chronic course, with a tendency to final recovery and recurrence. It seldom went on to destruction. Dr. Verhoeff considered the treatment of tuberculosis of the eye as very satisfactory. He used only the old tuberculin, and he had gotten good results. He thought it essential to get a reaction, either general or local. The patient already had resistance, and all he needed was to have his resistance stired up. The amount of reaction with the diagnostic dose would give a clue as to the size of dose to use in treatment. Dr. Verhoeff discussed the relation of phlyctenular conjunctivitis to tuberculosis. Histologically the phlyctenules resembled tuberculosis. The condition was associated with adenitis and acne of the face. Tubercle bacilli had never been found in these phlyctenules, but there was probably no doubt that they were tuberculous. He had suggested that the recent work on anaphylaxis might explain these cases.

Tuberculosis of the Ear.—This paper by Dr. Clarence John Blake of Boston was read by Dr. H O. Reik of Baltimore. The clinical aspects of tuberculous infection, as manifested in the middle ear, and the consequences evidenced in advanced implication of the temporal bone, had been described by the earlier

writers on otology, but it was only within the past ten years that more precise attention had been given to a form of invasion of the middle ear and labyrinth, characterized by considerable and rapid destruction of all tissues, this being coupled with a peculiar lack of preliminary subjective symptoms. The accessibility of the middle ear cavity to infection, through the medium of the tympanopharyngeal tube, and the character and location of the soft tissues of the epitympanum, explained the more common implication of this cavity, while the peculiarity of the objective symptoms emphasized the importance of aural examination for purposes of differential diagnosis.

Dr. Minor of Asheville, N. C., said that he saw a great deal of tuberculosis, and there was a small number of these patients who suffered with a chronic otitis, generally discharging, and in whom he had been unable to find any means of determining whether they were suffering with tuberculosis of the ear or not. He generally handled them on that assumption, but he wished to ask Dr. Reik what means there were of telling whether these cases were tuberculous or not, and also whether they had the same danger as the ordinary suppurative middle ear cases.

Dr. Reik said that tuberculous suppuration of the middle ear was not so dangerous as suppuration due to pyogenic organisms. Only a very small percentage of the cases that developed intracranial complications had shown a tuberculous history. As to diagnosis, tuberculosis of the ear generally occurred in advanced pulmonary tuberculosis, and a general examination would show a tuberculous condition of the lungs. An examination of the pus usually showed a mixed infection. Even if tubercle bacilli were found, we were apt to find also the streptococcus or the pneumococcus present. Whether we could hope for any help from the tuberculin test or the skin test, he could not say.

SECTION ON TUBERCULOSIS IN CHILDREN.

First Day—Monday, September 28.

The President, Dr. Abraham Jacobi, of New York, in the Chair.

President's Address.—Dr. Abraham Jacobi, of New York, read this, the Presidential address. He said that America had seen during a few decades many large and influential meetings, both national and international. They were dedicated to various interests, scientific and commemorative, war and peace. The grand exposition and congress of St. Louis in 1904 combined in twenty sections whatever appeared to a thoughtful and energetic central committee to be most appropriate in bringing together the best thought of the world. As to-day, great men reached our shores over the ocean, which had become a connecting bridge after having proved a severing gulf, to exhibit their own and other's achievements, and succeeded in furnishing a comprehensive and lifelike exhibit of the present conditions of sciences and arts in their influence on the cultural labor of mankind. While in this way the intellectual and social interests of the world were displayed and fostered, the normal and destructive instincts of brute man were also studied and their dire results held up to view, in the peace congresses of this and other countries. Evidently mankind was more active in the attempt to rid itself of its savage past and to develop a human future on the basis of the impulses of its heart and the dictates of its brain. If there be any concourses of more merit and endowed with more beneficent influences in shaping the future of our race than even peace congresses, it was the series of congresses of hygiene and demography, and principally those on tuberculosis, which had met during the last two decades. Representatives both of the medical professions and of the intellectual lay public of all civilized nations convened with a sternly expressed demand that there must be an end to the hecatombs of victims of the cruelest enemy of our race, which could not be combated except by an aggressive movement on the whole line. Altogether, the fight against infectious and contagious diseases was no longer a strictly medical matter. What the active practitioners and the laboratory experts could do they had accomplished. The nature of anthrax, diphtheria, scarlet and typhoid fever had been recognized and proclaimed, *urbi et orbi,* and preventatives had been found and advised. If governments and their employees had in many cases, and not in the least in our country, neglected their warnings and active measures, they, the physicians, had mourned and their fellow citizens had suffered. For, though they had the knowledge of the causes of typhoid fever at their finger's end, vigorous men, before they ever saw an enemy, had died in untold numbers in camps, and towns and country had been devastated by it, though it belonged to a class of easily prevented epidemics. Hundreds of endemics and epidemics of scarlet fever and diphtheria had followed the track of infected foods, and hundreds of thousands of promising infants and children were swept away annually by decomposed and infected milk. Tuberculosis had proved the deadliest and most obstinate enemy of them all. Its onset was insidious, its course frequently not suspected or watched, its invasion not prevented on account of the neglect of mucous membranes, its development insured by depressed vitality, its curability ignored, and its fatal termination more feared than palliated.

This section was dedicated to the etiology, prevention and treatment of tuberculosis in children, but did not discuss the mooted question of whether pediatrics deserved a place among the specialties in medical practice. Their problems were more direct. Was the tuberculosis of infancy and children exactly like that of advanced years? What was its frequency? Were most cases of tuberculosis of the adult preformed in the child, as it had been claimed? Did tuberculosis depend on milk alone, or in the majority of the cases? Or had milk feeding little or nothing to do with its origin? What was the difference between bovine and human tuberculosis? How was milk to be treated? Was it to be administered raw, pasteurized, scalded, sterilized, pure, or diluted or mixed? What had the udder or the mamma to do with it? These and many other questions were placed before them in the syllabus Dr. Jacobi distributed a year ago. The relation of the physician to the treatment of tuberculosis was twofold. As the medical adviser of the individual patient, he looked for his comfort, advised him in regard to his diet and other hygiene, selected a sanitarium, counseled change of occupation, and utilized other therapeutic measures. There were many symptoms to be relieved or removed, the power of vital resistance to be increased, the circulation to be strengthened, the digestion stimulated, and nutrition improved by hydrotherapy and by medication with arsenic, digitalis, guaiacol, or bone-marrow. Rest and food, and air, and change of air were ever so many steps in the right direction. It was true that, while what they accomplished was frequently the restoration of perfect health, it was, however, in too numerous cases life only without health that was preserved. But the individual had a right to live and to command their efforts to save and to invigorate him. It was not their fault when the average vigor of human society was undermined by the accumulation of numberless invalids who were kept alive. In such situations the subjects of their exertions were sick individuals who insisted upon salvation from death, and demanded that their lives be prolonged, though they be less than normally competent. It was characteristic for misanthropic critics to blame them for preserving inferior individuals, but not to object to wholesale destruction. No infectious disease ever left the people in so low a physical, moral, or economic condition as a war of equal duration or ferocity. At best the recovery of the tuberculous individual

was difficult, and too often doubtful. That was why prevention was a more thankful task. Too often, when the tuberculosis specialist was consulted, the preventive and curative measures of the family practitioner who was not consulted were no longer within reach. What the latter was doing for the individual or the family, medical science and the profession at large had been and were doing for the sanitary condition of the public at large and the community through well directed literature, through boards of health, and through legislation. This whole congress had reserved a whole section to the consideration of state and municipal control of tuberculosis, and of laws and ordinances relating to it. The time was approaching when the people would insist upon having its health safeguarded by the public recognition of its claims. They had no central representation of the forces that made for the physical welfare of the people and no United States board of health in the advisory cabinet of the first employee of the nation. That was why the people in their democratic and self-determining methods were gathering in societies, attempting and attaining what in many other countries it took the powers of the governments to accomplish. That was why a congress like theirs invited the public at large, and the national and foreign governments, to share the labors and responsibilities of the medical professions of the world. Nothing proved to better advantage the interdependence of the several parts of the social organism, or the absolute impossibility of one man, or one class of men, to pass a hermit life and prove useful. The individual physician deteriorated when in solitude. Intercourse with his peers corrected his ignorance, which, as the sick around him had to suffer from it more than he, was sinful. No progress was ever evolved from castes, classes, or ruts. Medicine must become a popular science. In this new century, universal ignorance of any people or race, even the white, should be esteemed an intolerable scandal, as it surely led to poverty and anarchy. It was not half knowledge that engendered superstition and lynching and sectarianism and faith cures; they originated from the same depth of darkness, *i.e.* total ignorance. As long as medical science would not enlighten the masses with its fundamental principles, it had failed in its most vital vocation. The simple facts of medicine should be taught in intelligent language in schools, from platforms, the pulpits, and last, by no means least, in newspapers. The first and best paid place on the editorial staff should be given to an all-around medical man, with no duty in life except to teach the millions of readers the axioms of physiology and hygiene, and their application to practical, every day life; they should no longer rely on the haphazard opinions expressed by medical men who were given no time to think or who were waiting for an opportunity to advertise themselves.

The unity of science had been preached this half century. Men and women must learn that hygiene was not curing, was no mere disinfection, but that it meant prevention, prevention in the life of the individual, the town, the nation, mankind. Their successes in exterminating tuberculosis, though they might have been marked, had been slow. In order to succeed fully, their work must be individual and collective.

Tuberculosis in Infants; An Analysis of One Hundred and Thirty-one Hospital Cases as Regards Etiology and Diagnosis, with Remarks Upon Prevention and Treatment.—Dr. Linnaeus E. La Fétra of New York read this paper. There were 73 pulmonary cases: 61 were proven to be tuberculosis by finding the tubercle bacilli in the sputum (necropsy also in 5); 1 by bacilli being found in the inspired air; and 11 by necropsy alone. There were 58 cases of meningitis tuberculosa; 57 were proven to be tuberculous by the tubercle bacilli in the spinal fluid (necropsy also in 5); and 1 by necropsy alone. Of the 58 cases of meningeal tuberculosis, the lungs were affected in 36; there were no physical signs in 8; there were signs of bronchitis in 20; there were signs of consolidation in 8; the tubercle bacilli were found in the sputum in 33 cases; tubercle bacilli were found in 8 cases without physical signs. There were 73 pulmonary and 58 meningeal cases, a total of 131. Tuberculosis occurred in the father in 12 of the pulmonary and in 11 of the meningeal cases, a total of 23; the mother was affected in 13 of the pulmonary and in 2 of the meningeal cases, a total of 15; an uncle or aunt was affected in 2 of the pulmonary and in 2 of the meningeal cases, a total of 4; other relatives were affected in 2 of the pulmonary and in 3 of the meningeal cases, a total of 5; a friend or nurse was affected in 2 of the pulmonary and in 3 of the meningeal cases, a total of 5; the room was infected in 1 of the pulmonary cases. These figures gave a total of 32 for the pulmonary cases (43.8 per cent.); 21 for the meningeal cases (36.2 per cent.); a total of 53, or 40.4 per cent. With regard to the location of the consolidation in 50 cases, the apex of the right lung was involved in 5 cases, that of the left in 3, a total of 8; the upper lobe of the right was involved in 4, that of the left in 5, a total of 9; the middle lobe was involved in 9 (plus 6) of the right; the lower lobe was involved in 13 of the right, in 7 of the left, a total of 20; more than one lobe was involved in 7 on the right, 6 on the left, a total of 13. This gave a total of 38 on the right side, 21 on the left side, a total of 59 minus 9, or 50. The location of cavities occurring in 5 cases showed the apex to have been involved in 2 cases on the right side; the upper lobe in 1 case and on the left side; and the lower lobe in 1 case on the right and 1 case on the left side.

The patients were all under three years, and the majority under one year of age. The mother, father or some one in close contact with the patient was found to have suffered from tuberculosis,—almost invariably pulmonary, in nearly half of the pulmonary cases and in over one-third of the meningeal cases. Of the meningeal cases more than half had pulmonary tuberculosis. It was impossible in the great majority of the pulmonary cases to make a diagnosis of tuberculosis from examination of the chest. Some cases gave no signs; many had simply generalized râles, while others had signs of broncho or lobar pneumonia; very few gave characteristic signs such as those of consolidation with adhesions or of cavity. The location of the consolidation was not characteristic. For an absolute diagnosis one must either find the tubercle bacilli in the sputum or see the lesions. A positive skin reaction in these young subjects was, however, almost certain. If careful sputum examination and the skin test were both negative, one could feel safe in ruling out tuberculosis, no matter what the signs in the chest. Of the 73 pulmonary cases, 34 died, 29 were unimproved, and 10 improved. Four patients seemed to have recovered completely, with no signs in the lungs from one to two years after leaving the hospital. Prophylactically, the mother and father in a tuberculous family should be warned, before the child was born if possible, that tuberculosis was communicated to the offspring by close contact, especially such as nursing a tuberculous mother and by kissing. As complete isolation from the afflicted person as possible, prevention from crawling on the floor, and the use of only washable rugs on the floor—these measures together with the usual hygiene should be enforced. Milk from untested cattle should be sterilized. All children of tuberculous families should be examined periodically for physical signs and for the tuberculin skin reaction. Suspicious cases should be at once put under active treatment, if possible in a country home, forest school or sanatorium. Persistent coughs in infants should be actively treated, lest tuberculous meningitis supervene.

Dr. Henry Koplik, of New York, said that if one examined the spinal fluid with diligence in cases of tuberculous meningitis they would find the tubercle bacillus in almost every case.

Dr. David Bovaird, Jr., of New York asked Dr. La Fétra how many examinations of the sputum were required in the cases he reported.

Dr. La Fétra replied that these examinations were repeated dozens of times; not only was one slide examined, but often as many as three. In answer to a question asking how he obtained the sputum, he replied in one of two ways. A soft rubber catheter was passed down to the lower part of the esophagus; the catheter was then pinched at the mouth and the tube withdrawn, with the mucus adherent. He preferred the second method, however. A piece of sterile gauze was fastened to a curved clamp, with the concavity pointing downward. With the baby's mouth opened, this was passed back and the glottis tickled, causing the baby to cough, and what came up came from the baby's lungs.

The Relation of Infectious Diseases, Measles, Whooping Cough, and Influenza to Tuberculosis in Children.—Dr. Edgar P. Copeland, of Washington, D. C., read this paper. He considered the subject important, because of the widespread nature of the disease. It was looked upon by the public with insufficient seriousness. Though tuberculosis was observed to follow measles, whooping cough and influenza as sequela and complication, it was difficult to determine the relation and the proportion of cases in which the relation was observed. Statistics showed tuberculous lesions in 31.2 per cent. of deaths from measles. The prevalence of latent tuberculosis was a subject of great importance. Catarrhal inflammation of mucous membranes, associated with hyperemia and lymphatic activity, common to all three diseases, was the key to the relation. Lymphatic activity determined a dissemination over the body. In the picture observed, usually general miliary tuberculosis, the pulmonary symptoms predominated. Influenza, although giving rise to many obscure chest conditions, seldom was followed by tubercle except when latent conditions existed. In conclusion he said that, considering the prevalence of measles, whooping cough, and influenza, tuberculosis did not follow sufficiently often to be of great importance, and its development in all cases was dependent upon a latent focus of disease, and its dissemination was directly due to lymphatic activity.

A Few Notes on v. Pirquet's Reaction in Children Under One Year of Age.—Dr. Carl Oscar Medin of Stockholm read this paper, which was discussed by Drs. Clemens von Pirquet of Vienna and Theodore Sachs of Chicago.

Second Day—Tuesday, September 29.

Report of a Case of Miliary Tuberculosis in a Child Aged Four and One-half Months.—Drs. A. L. Klotz and E. M. Green of Easton, Pa., reported the case of a female child who was born in December, 1907. At the age of two weeks the baby was fed on cow's milk; at the age of four weeks she was given certified milk modified. The baby gained steadily until twelve weeks old, when she began to gradually lose flesh. Her temperature averaged 99.4° F., her abdomen became much distended, and she died when four and a half months old. The lungs contained two small nodules only, and one or two mediastinal glands were involved. The peritoneal cavity was completely obliterated, and the intestines were firmly glued together. The tuberculous foci consisted of a mass of tubercles fused into flat yellowish masses the size of lentils. In the pancreas these masses were numerous, completely disorganizing the organ. This was a rare condition, for the pancreas was seldom involved. In the intestines the tubercles were entirely confined to the serous and subserous coats, and these were completely packed with tuberculous deposits. The muscular layers and mucosa were atrophied with small-celled infiltration. The tuberculous masses consisted of lymphoid and epitheliod cells surrounding small foci of coagulation necrosis; the giant cells were rare. The tubercle bacillus was most abundant in the epitheliod layer and on the outer surface of the necrotic foci. They were found to be almost absent in the necrotic tissue and near the giant cells. Most of the bacilli were shorter, thicker and less beaded than the ordinary bacilli found in human tissue. Investigation showed that the farm from which the first milk was obtained, although carefully managed and inspected, had one or two infected cows. They were highly bred Jersey cattle. The certified milk came from ordinary healthy inspected cattle, among which no infected cows were discovered. The child evidently became infected during the third and fourth weeks of life and so violently that death occurred three months later.

Report of Miliary Tuberculosis with Tuberculous Meningitis in an Infant Seventeen Weeks Old.—Drs. C. A. Fife and D. J. McCarthy of Philadelphia made a report of this case. The patient was a baby seventeen weeks of age, in which there was an attack of tonsilitis shortly after birth. This was succeeded by a gastrointestinal infection, with enlargement of the spleen. The principal clinical symptoms were drowsiness, stupor, transient third nerve palsy, facial contractions, rigidity of the extremities and convulsive seizures. At the autopsy an extensive miliary tuberculosis was present, affecting all the organs of the body. The source of infection in this case was in all probability from an old lesion at the apex of the right lung. In this location there was a cavity 2 cm. in diameter, with an area of caseous degeneration extending from this cavity to the seat of the right lung. The peribronchial glands were enlarged and caseous. The mesenteric glands were enlarged and were the seat of caseous degeneration. This case would appear to be one of intestinal infection with secondary involvement of the lung with primary miliary and secondary meningeal tuberculosis.

The Clinical Manifestations of Tuberculous Meningitis.—Dr. D. J. McCarthy of Philadelphia read this paper and considered the following types of atypical cases: Tuberculous meningitis as a local manifestation of tuberculous bacteriemia. Irregular fleeting palsies, especially of the eye muscles, blindness, and dilation of the pupils from internal hydrocephalus; stupor and delirium helped to distinguish this type. Minor tuberculosis and septic infection; here the cranial nerve involvement was very limited, but the pulse rate was apt to be high. Localized tuberculous meningitis, which was to be distinguished by the localizing symptoms in a case of pulmonary tuberculosis. Productive and healing types showing pathologically small tubercles with a spindle-shaped type of cell. These were the fulminating types with hemorrhage. Cases associated with traumatism, those which were of considerable medicolegal value. The purpose of his paper was to call attention to the fact that the source of infection must be discovered and the laboratory diagnosis should be valued as of secondary importance.

Tuberculosis in Children, Particularly with Reference to Tuberculosis of the Lymphatic Glands.—Dr. Theodore Shennan of Edinburgh presented this communication. Tables epitomized the results of an investigation of the post mortem reports of cases of tuberculosis in children who had been in-patients in the Royal Hospital for Sick Children, Edinburgh. Out of more than 1,000 post mortem examinations, 407 were made upon children dying from tuberculosis, and these tables were based upon the last 307 of those cases. The important facts brought out referred to the frequency of occurrence of the disease in lymphatic glands, and to the dissemination of tuberculosis from these glands. (1) These glands were affected in a very large proportion of the cases, 77.8 per cent. (2) The thoracic glands were more frequently implicated than the abdominal. (3) Excavation of the lungs was comparatively infrequent. (4) In tuberculosis of the abdominal glands, 50 per cent. were unaccompanied by ulceration of the intestine, and in two-thirds of the cases in which there was ulceration of the intestine there was no excavation of the lungs. (5) In 60 cases altogether (19.5 per cent.) ulceration of the intestine was present, without any previous excavation of the lungs. (6) In 137 cases

(44.6 per cent.) death was immediately due to tuberculous meningitis, and this appeared to follow dissemination from caseous glands, especially thoracic, in the vast majority of instances.

The Primary Localization of Tuberculosis in Children.—Dr. Woods Hutchinson of New York said that the data so far collected appeared to point toward the following conclusions: First, that the frequency of pulmonary tuberculosis in children was much greater than was formerly supposed. Second, that the lung was the most frequent site of tuberculous involvement in children, as in adults. Third, that whatever the port of entry, the lung suffered most severely and most frequently. Fourth, that instead of tuberculosis having a special preference for the bones, joints and glands in childhood, the tuberculous process in these regions and tissues would appear to be secondary to the involvements of the lung and to represent a residual stage of a generalized infection. Fifth, that it would appear probable that even the glandular forms of tuberculosis did not represent an earlier or milder form of the infection, but were secondary to a pulmonary involvement. Sixth, that the moderate but appreciable degree of immunity against pulmonary tuberculosis possessed by children who have manifested osseous, articular, or glandular forms of the disease was possibly to be interpreted on the theory that they had already survived a considerable degree of pulmonary involvement. Seventh, that such immunity as might be acquired by civilized races was probably like the immunity of the negro races to malaria—the result of the survival of attacks of the pulmonary form of the disease in childhood. Lastly, that the field in which the decisive battle of our future campaign against tuberculosis must be fought was the home; our chief enemy, infection in early childhood; our heaviest gun and our most crying need, camps, "preventoria," for the reception and cure of infected or exposed children before they had become unmistakably tuberculous.

The Distribution of Tuberculous Lesions in Infants and Young Children; A Study Based on Post-mortem Examinations.—Dr. Martha Wollstein presented this study. Among 1,131 autopsies on children under four years of age, 185 showed tuberculosis. Whereas of all autopsies performed on infants less than one year old, tuberculosis affected 12 per cent. at that age. During the second year of life 33 per cent. of all who came to autopsy had tuberculosis, and of those older than two years 34 per cent. Four cases were less than three months old, the youngest being seven weeks. There were no cases of congenital tuberculosis. In one instance the only tuberculous lesion was found in the bronchial glands; in four the lungs alone were involved, and in thirteen the lungs and bronchial glands. There were seven cases of primary infection of the digestive tract, including two cases of mixed deglutition and respiratory origin. Of the more advanced and generalized cases only two gave evidence of probable intestinal origin, while forty began in the respiratory tract. In the majority of the cases of extensively generalized tuberculosis in young children, the exact point of entrance must remain in doubt. Although the lungs were involved more frequently than any other organ, this proved their marked predisposition to tuberculosis rather than their primary infection. Nevertheless, cases of respiratory origin predominated over those of indigestion.

The Relative Frequency of Abdominal Tuberculosis in Great Britain and the United States.—Dr. David Bovaird, Jr., of New York read this paper and presented some charts of interest and one in particular showing the frequency of primary intestinal tuberculosis as determinded by post-mortem examinations. In Great Britain Carr reported 120 examinations, with 20 cases of definitely primary intestinal tuberculosis; Woodhead reported 127 examinations with 14 cases; Guthrie 77 examinations with 19 cases; Still, 269 examinations with 63 cases; Ashby, 155 examinations with 20 cases, and Shennan 413 examinations with 100 cases, a total of 1,161 examinations and 236 cases of definitely primary intestinal tuberculosis, a percentage of 20. In the United States, on the other hand, Northrup reported 125 examinations with 3 cases; Holt, 119 examinations with no cases; Bovaird, 125 examinations with 2 cases; Hand, 115 examinations with 10 cases; Foundling Hospital (unpublished), 136 examinations with 6 cases; a total of 620 examinations and 21 cases of definitely primary intestinal tuberculosis, a percentage of 3.5. Other charts showed the percentage of abdominal tuberculosis and tuberculous meningitis in three Great Britain hospitals—the Royal Hospital for Sick Children in Edinburgh; the Hospital for Sick Children, Great Ormond Street, London, and the Royal Hospital for Sick Children in Glasgow. He also showed the percentage of abdominal tuberculosis and tuberculous meningitis in the Babies' Hospital and the Post Graduate Hospital, New York, and the Children's Hospital in Boston. A great discrepancy was noted in these figures. Abdominal tuberculosis was eight times more frequent in Great Britain than in the United States. This discrepancy in the figures between Great Britain and the United States was the same as between Great Britain and France or Germany. There were, in fact, three times as much tuberculosis of all types in Great Britain than in the United States. Dr. Bovaird said he did not know where to turn for an explanation for such a discrepancy in the figures.

Tuberculosis of the Pericardium in Children.—Dr. Joseph S. Wall of Washington read this paper. He said that the occurrence of a group of cases of marked influence in the production of clinical symptoms, warranted the consideration of tuberculous pericarditis as a distinct morbid entity. This term might be used in such cases, while to other cases, characterized by their latency, which occurred as an incident in tubercular disease, might be applied to the designation, tuberculosis of the pericardium. The distinction, however, was but one of degree. The infectious diseases of childhood had an etiological influence which was distinctly suggestive, and such influence was to be attributed largely to the adenopathy of the mediastinal glands which followed in their wake. As a direct causative factor stood foremost tuberculosis of the tracheobronchial and peribronchial glands, with extension of the disease to the pericardium by continuity and contiguity of tissues. The process might be plastic; it might be associated with small or extensive exudates which were frequently hemorrhagic or, as a final outcome, symphysis of the leaflets might occur. He took up a consideration of the symptoms, prevention, and treatment and made a report of two observations made with autopsies.

Intermittent Albuminuria of Childhood Considered in Its Relation to Hereditary Tuberculosis.—Dr. J. Teissier, Professor of Clinical Medicine at the University of Lyons, read this paper and offered the following conclusions: Hereditary tuberculosis might attack the kidney in the child or in the adult in one of two ways: 1. Certain individuals presented a more or less abundant albuminuria, which was preferably intermittent, and which might affect one of the well-known classic cycles; but it disappeared as the pulmonary localization became established, or gave rise to general lesions, and might, therefore, be termed pretuberculous albuminuria. This form of albuminuria did not necessarily imply the existence of renal tuberculosis; but, on the contrary, seemed to have a toxic origin, and resembled the bacteriolysis which was an expression of the spontaneous defensive forces of the organism. As soon as this spontaneous destruction ceased tuberculosis developed, and the albuminuria came to an end. 2. The second series of cases was much more numerous. The kidney was affected in a peculiar manner, which they had been able by a long series of similar observations to determine almost with certainty; the kidney reacted very slowly and sluggishly to the action of the tuberculous toxin transmitted by the parent, and a slight degree of latent

nephritis was produced which resulted in a very relative impermeability, relieving itself in a moderate diminution of the total molecular diuresis, an increase in the coefficient of Korany, and also in a slight elevation of the blood pressure; a moderately severe albuminuria, usually intermittent; either of the matinal (morning) type, or frankly orthostatic (present during the active hours of the day); and finally—as the hall-mark of its tuberculous origin—a well-defined d'Arloing-Courmont serum-reaction often exceeding 1-15th. These cases, which made up more than 34 per cent. of our statistics of intermittent albuminuria in young subjects, did not eventuate in actual tuberculosis. For this reason they seemed to justify the term paratuberculous albuminuria, and many of these cases belonged to the category of spontaneous immunization, to which Professor Courmont had recently called attention.

(To be continued.)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE MUSCLES OF THE EYE. By LUCIEN HOWE, M.A., M.D. 8vo, 468 pages, illustrated; cloth. G. P. Putnam's Sons, New York.

THIRTEENTH ANNUAL REPORT OF THE COMMISSION OF PRISONS FOR THE YEAR 1907. 8vo, 341 pages; cloth.

CHOLECYSTO-PANCREATITE. ESSAI DE PATHOGENIE. By le Docteur REINE MAUGERET. 8vo, 150 pages, illustrated; paper. G. Steinheil, Paris.

DISEASES OF THE SKIN. By GEORGE THOMAS JACKSON, M.D. 8vo, 737 pages, illustrated; cloth. Lea & Febiger, New York.

CATARACT EXTRACTION. By J. HERBERT CLAIBORNE, M.D. 8vo, 169 pages, illustrated; cloth; $2.00 net. William Wood & Company, New York.

ESTIMATION OF THE RENAL FUNCTION IN URINARY SURGERY. By J. W. THOMPSON WALKER, M.B., C.M. (Edin.), F.R.C.S. 8vo, 274 pages, illustrated; cloth. Cassel & Company, Ltd., London.

INDUSTRIAL AND PERSONAL HYGIENE. By Dr. GEORGE M. KOBER, M.D., LL.D. 8vo, 175 pages, illustrated; paper. The President's Homes Commission, Washington.

THE THIRTEENTH, THE GREATEST OF CENTURIES. By JAMES J. WALSH, M.D., Ph.D., LL.D. 8vo, 436 pages, illustrated; cloth; $2.50 net. Catholic Summer School Press, New York.

THE POPES AND SCIENCE. By JAMES J. WALSH, M.D., Ph.D., LL.D. 8vo, 430 pages; cloth; $2.00 net. Fordham University Press, New York.

MEDICAL GREEK. By ACHILLES ROSE. 12mo, 262 pages; cloth. Peri Hellados Publication Office, New York.

THE EXTRA PHARMACOPŒIA OF MARTINDALE & WESTCOTT. By W. HARRISON MARTINDALE, Ph.D., F.C.S., and W. WYNN WESTCOTT, M.B. (Lond.), D.P.H. 32mo, 1,164 pages; 10s 6d net. H. K. Lewis, London.

REPORTS OF THE COLLIS P. HUNTINGTON FUND FOR CANCER RESEARCH OF THE GENERAL HOSPITAL. 8vo, illustrated; paper.

BULLETIN DE L'ASSOCIATION FRANCAISE POUR L'ÉTUDE DE CANCER. By PIERRE DELBET and R. LEDOUX-LEBARD. 8vo, 58 pages, illustrated; paper. Felix Algan, Paris.

PATHOLOGICAL TECHNIQUE. By FRANK BURR MALLORY, A.M., M.D., and JAMES HOMER WRIGHT, A.M., M.D., S.D. 8vo, 480 pages, illustrated; cloth; $3.00 net. W. B. Saunders Co., Philadelphia.

PULSATING EXOPHTHALMOS. By GEORGE E. DE SCHWEINITZ, M.D., and THOMAS B. HOLLOWAY, M.D. 8vo, 124 pages; cloth; $2.00 net. W. B. Saunders Co., Philadelphia.

DIAGNOSIS BY THE URINE. By ALLARD MEMMINGER, M.D. 12mo., 116 pages; illustrated; cloth; $1.00 net. P. Blakiston's Son & Co., Philadelphia.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City for the week ending September 26, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	530	172
Diphtheria	255	24
Measles	54	—
Scarlet Fever	143	7
Smallpox	—	1
Varicella	17	—
Typhoid Fever	127	29
Whooping Cough	25	6
Cerebrospinal Meningitis	8	8
Malarial Fever	—	—
Totals	1159	247

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending September 25, 1908:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.
California, San Francisco	Aug. 29–Sept. 5	2	..
Indiana, Indianapolis	Sept. 6–13	7	..

THE DUTIES OF THE MEDICAL PROFESSION TO THE PUBLIC.*

BY M. ALLEN STARR M.D., LL.D., Sc.D.,

NEW YORK,

PROFESSOR OF NEUROLOGY, COLUMBIA UNIVERSITY.

YOUR presence here to-day to receive your welcome to the medical school is proof that you have weighed carefully the attractions offered by the various learned professions and have chosen medicine. It is therefore needless for me to put before you the reasons for such a choice. It may be that you have been drawn to it by the opportunities it affords for purely scientific investigation, or it may be that the application of the science to the art of relieving human suffering and benefiting humanity has appealed to your best instincts.

The search for conditions leading to diseases, whether of an infectious type or of the numerous sporadic types may excite your interest. These scientific investigations are fundamental. The discoveries of the bacteriologist, who finds in the laboratory by the aid of the microscope the minute organisms which produce so many diseases; who cultivate these little plants in appropriate soil, watching their blossom and fruitage and seed, as he can do in the study of malaria, and who transplants these bacteria, thus finding out the conditions favorable to their life or disastrous to their reproduction, may well stimulate your scientific imagination. The facts that these bacteria growing in the human body produce changes in that body of a special kind, causing, on one hand, symptoms that we recognize as peculiar to each kind, and, on the other hand, effects in the blood which we now regard as instinctive efforts of nature to kill the bacteria or to counteract their effect by producing an antidote,—all these facts and many other problems worked out in the laboratory by purely scientific methods afford a field of labor for those of you who are thus disposed.

You may, on the other hand, have the more immediately practical side of medicine in view. You may have seen the physician, calm, of keen judgment and sure insight, come to the bedside of some one dangerously ill and by his skillful direction, by his hopeful confidence, and by the use of remedies combat the symptoms and guide the patient through the illness to restored health and vigor. You may have known the surgeon, prompt to use means which seem at times cruel or daring, secure by his operative skill a rapid relief from conditions otherwise surely fatal. And this direct action for the saving of human life may be the thing which inspires you with enthusiasm and makes you feel that your work is the most practical and useful in the world. Or you may have the literary inclination of the scholar who is fascinated by the records of achievement in some of the many fields of medicine and who delights in tracing the progress of knowledge, in gathering together the thousand and one facts which are scattered through various books in different languages, in bringing these facts into an orderly sequence and in presenting in concise and accurate form the sum total of knowledge on that subject, thus making accessible to every one the labor of many investigators through many years. Surely such a writer, the author of monographs and books on medicine, does much to disseminate information and is a most useful member of his profession.

The widely varied character of the work open to you, the possibility of a choice among many different interests and activities provides an outlet for your varied energies which I have no doubt you fully appreciate. The opportunities of specialization are so numerous in medicine that there is hardly any taste which cannot be satisfied.

It is not of these things, however, that I wish to speak to-day. In your future course of study you will appreciate these various phases of the physician's opportunity more and more. The thing I wish you to realize particularly is that in studying medicine you are becoming leaders and directors of the public in those matters which most nearly relate to their material and moral welfare. The duty of the physician to the community is an active element in life to-day, and it is one whose value is being more and more appreciated. The result of these past years of scientific research and of wonderful discoveries regarding the nature and causes of disease has been to reveal many important facts that have a direct and practical bearing upon the prevention of disease. Prevention is not a matter for the physician; it is a matter for the ordinary citizen to strive for, and the citizen must be informed. He needs instruction. He sees its importance. He is willing to accept it. He is eager to apply it; if it is to keep him well or to save his children from disease and death. Here, then, is a field of labor waiting for you. Put the facts at your command before the public and it will soon appreciate the necessity of acting under your direction. Instruct them in regard to the prevention of typhoid fever by proper drainage and care in securing pure drinking water, and they will demand and secure immunity from this disease. Convince people of the need of vaccination to prevent smallpox, of the need of prophylactic injections to prevent tetanus, of the need of the immediate use of antitoxin injections of diphtheria, of the necessity of isolation of cases of infectious disease, and they will see the reason for these things and will promptly adopt the suggestions you give. Impress upon the community the facts regarding tuberculosis; the enormous mortality of this disease, which still continues to affect a quarter of the race and kills 15,000 persons yearly in this city, the possibility of its control, if its dissemination is prevented, if it is promptly cared for, and

*Opening Address to the Students of the College of Physicians and Surgeons, Medical Department of Columbia University, September 25, 1908.

if the infected persons are given specific directions regarding their manner of life, and the community will in the end welcome the knowledge. It is true that there are always ignorant or fanatical or prejudiced persons who oppose scientific progress and shut their eyes to danger. But the world as a whole is everywhere dominated by the intelligent section of the community. And just as Jenner's vaccination for smallpox has in a century fought its way to general acceptance, though at first it met with violent opposition, and just as Lister's antiseptic or aseptic methods of surgery have within thirty years revolutionized surgery, making possible hundreds of operations hitherto unheard of and thus have saved and will save millions of lives, so we may believe that proper methods of handling tuberculosis will within the next quarter of a century eliminate that scourge from the human race. The plagues of the middle ages have been vanquished and this modern plague is in a fair way to follow them. It is part of your duty to bend your energies to this great work, not only by applying your skill to the relief of those many forms in which the disease shows itself, but more especially in giving the widest dissemination to those facts which bear upon the prevention of its development and spread. Then you will perform a most widely useful service, not merely in some small community or city as a practicing physician, however large your practice, but to the world at large, which is made up of the small communities which you can reach.

This is the age of publicity. The idea of mystery in science is exploded. There are no secrets in medicine. The use of a dead language in writing our directions is destined soon to be given up. There is a demand for open facts and clear statements. And no one can present these facts so well as the expert who knows the subject. You will here learn to be such experts. You will acquire all the knowledge of disease, of its causes, of its remedies, of its prevention, which can be had. Remember that it is a large part of your duty to make this knowledge available to others, not merely by your efforts as physicians in the care of sick persons, but by your activity as citizens in your land in the care of its people.

The necessity of proper directions of the public health has already been recognized by the establishment everywhere in our country of officers and boards of health. In many cases these are most efficient, as, for example, in the City of New York, where the best talent in the profession is devoted to this service. In many other places such health officers are mere political dummies, holding the offices for their salary and being of no influence and little use in their communities. It is important that the public should be shown how great is the responsibility of such health officers; how important and useful is their sphere of operation and how necessary to the community is a well-organized board of health in every place. Such health departments are doubly necessary at the present time when the diagnosis of many diseases depends on bacteriological or pathological examinations only possible in a laboratory and impossible for the individual to carry out. Every health officer in every small community should be in close relation with a well-equipped laboratory under a special expert in the nearest city, so that there shall be no delay in the investigation of diphtheritic, typhoid, or tubercular excretions, or in those blood examinations now essential to diagnosis and to treatment. The establishment of such laboratories in all towns is a necessity, and this fact with the need of ample endowment by the State is a matter to be urged upon the State legislatures. By exerting your influence in spreading the information among the public; in making clear the need of State supervision and aid in providing proper facilities for the boards of health and in demanding pure water supplies, clean milk supplies, perfect drainage for towns, sanitary inspection of tenements and sweatshops and the prevention of overcrowding in lodging houses, and the separation of patients suffering from infectious and contagious disease, you can do much to benefit public health.

I turn now to another sphere of activity open to you and loudly demanding the efforts of the medical profession, namely, the prevention of diseases of occupation by legislative enactment. You may say, Why invoke law to treat disease? Can we not as physicians handle it? Is it necessary to appeal for aid to law givers who are not always intelligent or safe allies?

When we study the poor patients who crowd our dispensaries and hospitals and who are often ignorant not only of the nature of their affections, but of the causes which produce them, we find a large number who have incurred the disease by reason of the character of their work. They are suffering from diseases incident to their occupation and which might perhaps under certain circumstances have been prevented. The number of industries in which lead poisoning is common is not generally known. Painters and plumbers and those who work on lead become impregnated by the lead, which soon affects the nerves and causes a form of paralysis, incapacitating the laborer for many months. Those who work out of doors are far less liable to this than those who work indoors, and when, as in certain factories, the lead is in the air, the room is close and not ventilated, it is the exception for the laborer to escape the poison. In the annual report of the chief inspector of factories in England in 1906 cases of lead poisoning are reported in the following occupations: File cutting, coachmaking, smelting of metals, printing, type founding and type setting, turning and enameling, whitelead manufacture, china and earthenware manufacture, especially glazing of pottery, lithographic work, manufacture of glass, of electric accumulators, of paints and colors, and shipbuilding. In 1899, 1,258 cases of lead poisoning were reported in England among these industries. But under the restrictive laws passed by Parliament and enforced, protecting the workmen in these industries, the number of cases had been reduced to 632 in 1906. Women, who seem to be more susceptible to lead palsy than men, have been excluded by law from such employment in England.

Manufacturers of looking-glasses and of silk hats, of barometers, of incandescent lamps, and of articles which are bronzed employ mercury in their trade and employees are exposed to the fumes of mercury in these factories as mercury volatilizes at a low temperature. If ventilation is not adequate, poisoning results, producing tremor and paralysis or even death. Arsenic is largely used in arts and manufactures, and unless great care is taken it produces serious forms of disease. In all dyeworks where it is used, in the preparation of wallpaper and artificial flowers, in the manufacture of white arsenic, in curing furs and in many other factories instances of arsenic poisoning are very common. Other metals, such as copper, zinc, and phosphorus, are equally poisonous, and the last named is a frequent cause of disease among those who produce matches. In many chemical trades the employees are exposed to various poisons, such as nitric acid fumes, aniline

dyes, sulphuric acid fumes, nitro-benzene gas, and many other substances given off in gases and vapors.

In addition to the occupations where poisons are taken into the body, there are many occupations in which the laborer is exposed to undue risks. Caisson disease is seen all the time in our hospitals, this being due to the sudden change from the high pressure to the low pressure of air incurred by the workman in coming out of the caisson where he has worked under a pressure of many atmospheres. Precautions are provided by having a series of chambers, each under a different pressure, but even this is not always enough to prevent this disease. The manufacture of explosives is attended by great risks, and the number of accidents in such factories is far greater than is ordinarily appreciated. Then there are many diseases due to organic or inorganic dust in the air that is inhaled, irritating the lungs, or is swallowed, producing affections of the stomach and intestines. In the great steel industries, which involve grinding and polishing of iron and thus throw minute iron dust into the air; in the textile manufactures, where cotton, silk, or jute is handled, and other fine particles are mingled with the dust; in cement making, flourmills, sawmills, tobacco factories, and many other industries it has been found that the percentage of deaths from consumption was much greater than in other employments where dust was not constantly in the air breathed. Sommerfield has shown that of 1,000 persons employed in occupations without the production of dust, 381 died of phthisis, while of 1,000 persons occupied in trades giving rise to dust, from 480 to 598 died of phthisis. Only 115 farmers in 1,000 die of phthisis. There is thus a distinct danger to those who are exposed to the inhalation of dust or of poisons in their various occupations. Now in England, Germany, France, and on the continent generally, it has been found expedient to pass laws protecting these exposed laborers so far as possible from the dangers of their occupations. A certain air space in workshops and factories is demanded. Regular ventilating apparatus with forced draughts to carry off noxious gases is required in those factories where chemicals are used or dust is inevitable, and where trades are particularly dangerous, as the making of looking-glasses, the glazing of pottery, special devices are required by law to obviate the evil effects. Inspectors of factories report regularly their discoveries of defects. The factory acts and the protection they afford to employees in England might be taken as models for our imitation. And even processes of manufacture which carry danger have been modified by law.

One specific case may interest you.* In Staffordshire over fifty thousand persons are employed in the manufacture of china and earthenware. Ten years ago the large number of cases of lead poisoning in this district caused so much comment and criticism that the Home Secretary appointed a commission to ascertain how the danger might be removed. That commission recommended that the percentage of lead could be much reduced in the glazes and in some could be eliminated. The manufacturers protested, maintaining that their methods could not be changed. The matter was finally arbitrated and the result was that lead employed in the process was reduced from 20 per cent. or 15 per cent. to 5 per cent., a monthly medical examination of workers was made obligatory, overalls and head coverings were provided and maintained by employers for women, respirators were to be worn by persons specially exposed, and the floors of workrooms were to be sprinkled and swept daily and a scheme of compensation for lead poisoning was arranged. Under these rules the trade has been working since 1903, and the number of cases of lead poisoning has been reduced over a half. This illustrates how legal enactment is necessary in some cases to enforce conditions that are needed for the prevention of disease.

*Diseases of occupation, by Thomas Oliver, M.D. E. P. Dutton & Co., 1908.

As you go about in your various fields of medical practice you will soon come in contact with labor conditions which you will see are of evil. In many cases a careful investigation will reveal the source of evil and lead you to find a remedy. It is your work to secure that remedy. Show the employer the condition; seek his aid in its correction. But if he will not act, then make known the condition to the public, initiate and promote public legislation in your local boards, in your State assemblies and senates. Bring these matters into notice, and you will be doing a strictly medical service not to your own patients merely, but to the community and to the country.

The laboring class needs our interest, our knowledge, and our effort in securing that adequate protection in their labor which is afforded them abroad. You are the men to inaugurate this work, and as physicians you must guide the public sentiment and supply the necessary information on which the needed laws must be based. We have a department of commerce and labor in our national government. We doctors must see that it does something more than to collect statistics regarding the trusts.

There is one other relation to the public that I wish to mention as one of the duties to which you are called. It is one that will carry responsibility, but that will repay your effort and it is one that, while giving you much satisfaction, is not to be estimated in terms of money. I mean your personal influence with your patients in aiding them by advice and counsel in those various critical times and emergencies which occur and recur in every one's experience. Fifty years ago, in our simpler type of life, the clergyman stood in the community as the one man of clean, high, unselfish mind, to whom one could safely go for disinterested advice and counsel. This is still so to some extent, and many members of the community who preserve their religious faith or who are devoted to their special church rely upon the clergy. The establishment of a personal relation between priest and parishioner best elaborated by the Catholic church, while open to criticism and abuse, is one which offers a great deal of help and comfort to many uncertain minds. But to-day there are many who have no church and no priest and yet need guidance in many ways. These turn for help to the physician and he is supplanting the clergyman as the one from whom to obtain counsel and advice. Your relations with your patients are likely to be very intimate. They will come to you in perplexity and in trouble for your personal view of their complex situations and for your aid or comfort. Learn to look impartially at all sides of a question. Keep your moral sense unclouded. Do not hesitate to uphold high standards. Never compromise with deceit and fraud. And let your own lives and conduct be such that your influence in the community shall be for the best, the purest, and the noblest. In this way only can you command the confidence of your patients and the respect of the public, which is essential if you are to guide them in their difficulties, safeguard their health and welfare, and be a benefit to them both materially and morally.

These, then, genetlemen, are some of the fields of activity opening before you as you enter upon your medical career. They are broad fields, with wide boundaries and far prospects. The soil needs be cultivated, but it will yield an abundant harvest to the persistent worker. The opportunities for your effort are varied. That effort is sure to be crowned with success. To add to the sum of scientific knowledge, to find some new means of bringing comfort, help, and relief to the suffering, to protect the ignorant and to guard the welfare of the public, these surely are objects worthy of your ardent enthusiasm and of your best endeavor.

THE PRESENT STATUS OF THE RADICAL MASTOID OPERATION FOR THE CURE OF CHRONIC PURULENT OTITIS MEDIA.*

By WENDELL C. PHILLIPS, M.D.,

NEW YORK.

The invitation to address the Medical Society of the Buckeye State at its annual conclave upon some subject relating to otology is an honor which I fully appreciate. In response to the invitation I submitted to your officers several topics, from which they finally selected the one which appears upon your scientific program, viz., "The Present Status of the Radical Mastoid Operation for the Cure of Chronic Purulent Otitis Media." My remarks will therefore be confined to purulent otitis media in its chronic form, and the methods for its relief. Even with these restrictions I have found it extremely difficult to arrange the material in such form as to present it in the brief time at my disposal.

Chronic purulent otitis media may be described as a chronic infective inflammatory process involving the structures of the tympanic cavity, with more or less persistent purulent discharge, and usually pathological changes in the mucous membrane and surrounding bone in the form of necrosis of some portion of the ossicular chain, tympanic walls, recessus epitympanicus, aditus ad antrum, antrum of the mastoid, the mastoid cells, or labyrinth. Cholesteatoma may or may not be present. We all know that the tendency to bone necrosis in chronic purulent otitis media renders it a complex disease, and one attended with difficulties in the way of treatment, extreme annoyance to the comfort of the individual, and considerable danger to life on account of the possibility of intracranial complications and lateral sinus thrombosis.

The line of demarcation between the acute and the chronic form of the disease may not be clearly defined. The persistence of an otorrhea beyond eight or ten weeks is, by common consent, considered to have assumed the chronic form.

In order that we may more intelligently consider the operative requirements, I shall briefly outline the etiology, pathology, and preventive measures of treatment.

Etiology.—In an otherwise healthy individual, with proper care and skilful treatment based upon modern methods, even though the disease results from some infection of virulent type, an acute purulent otitis media should always be recovered from in from two days to three weeks, the exceptions to this rule occurring in tuberculosis, syphilis, or malignant cases. It is my personal belief that if all acute cases be subjected to proper treatment, the disease in the chronic form would be almost unheard of. Without wishing in any manner to reflect upon the medical profession in general, it still remains a fact that this disease usually results from neglect or unskilful treatment of acute attacks or from failure to prevent recurrences by maintaining good general health, caring for intranasal infections and deformities and the removal of diseased adenoid tissue and hypertrophied tonsils in young children. Primarily the undergraduate college is at fault in not providing adequate facilities for instructing students in the actual diagnosis and treatment of the diseases of the ear, nose, and throat.

Chronic purulent otitis media may result from a single attack or a series of recurring acute attacks; in most instances, however, some complication, either a mastoid or at least an involvement of the mastoid antrum, has accompanied the acute infection. It is probable that a large proportion of all chronic cases have at some time had mastoiditis from which recovery has taken place without operation, but with loss of hearing, chronic offensive discharge, and all the dangers attending chronic bone necrosis. A simple mastoid operation promptly performed prevents all of these serious sequelæ and almost without exception gives perfect hearing results.

A series of predisposing factors enter into the history of every case. The most prominent of these are disease and hypertrophy of the lymphoid tissue in the vault of the pharynx and of the faucial tonsils. Recurrent attacks of otorrhea in young children are always an indication of the presence of adenoids and hypertrophied tonsils. Intranasal infections and deformities must also be duly considered. Acute infectious diseases, especially those peculiar to childhood, together with grippe, diabetes, syphilis, and tuberculosis, form a distinct class of predisposing factors. This is partially due to the virulency of the infection which accompanies them, and also to the systemic depression which is present. Such aural complications as involvement of the epitympanic space, aditus ad antrum, and mastoid antrum strongly predispose to the chronic condition, and especially so in patients who do not receive proper care and treatment. The type of infection is also an important etiological factor, a streptococcic invasion always giving a virulent type to the infective process.

Pathological changes in the chronic purulent type of inflammation are referable either to the soft tissues or to the bony surroundings. When confined to the middle ear mucosa the membrana tympani becomes partially or wholly destroyed. The inflammatory process may involve the entire intratympanic mucous tract or it may remain limited to certain localized areas. The tissue changes consist in swelling, connective tissue inflammation, granulations, polypoid degeneration, and ulceration. In the more severe forms necrosis takes place, involving one or more parts of the middle ear, and always attended with pus discharge. Bone necrosis may be confined to the ossicular chain, but as a rule the tympanic ring and bony walls of the tympanic cavity gradually succumb to the necrotic process. Unfortunately necrosis is prone to extend through the aditus into the mastoid antrum and the mastoid cells. Even the petrous portion of the temporal bone which contains the cochlea and semicircular canals is not exempt, and herein lies one of the dangers of the disease. Bone necrosis may be considered the danger signal of chronic purulent otitis media. The span of bone between the roof of the attic and mastoid antrum and the

*Read before the Ohio State Medical Society, May, 1908.

middle cerebral fossa is not great. Fortunately it possesses two firm walls through which the necrotic process must pass before entering the cranial cavity. The same holds true in regard to the enormous blood channel, the lateral sinus, which passes in close proximity to the mastoid antrum, although beneath the inner bony table. Loss of substance involving both the soft tissues and bony structures is a common pathological change observed within the tympanic cavity. Perforations of the membrana tympani, varying in size and location, are always present.

Symptoms.—Unlike acute purulent otitis media, an extensive and prolonged purulency may exist with entire absence of pain. Whenever pain is present it is an indication either of some slight obstruction to the normal pus flow or to the commencement of some more serious complication associated with an extensive purulent process. Disturbances of hearing, all the way from slight to complete deafness, are present in every case. The chief symptom of the affection is a constant flow of pus from the external auditory canal. When bone necrosis is present the pus will possess the carrion-like odor indicative of this condition. In a limited percentage of cases there is a formation of cholesteatoma. In my experience the percentage of true cholesteatomatous cases in this country is extremely small. When present, large masses of cholesteatoma exfoliate at intervals after which relief of symptoms will take place. Fever is rarely present in uncomplicated cases. Recurrent attacks of mastoiditis are sometimes observed, and when sinus thrombosis, pyemia, meningitis, or brain abscess develops, the typical symptoms of these complications make their appearance.

Diagnosis.—The diagnosis is based upon the history of prolonged otorrhea and upon the otoscopic findings. Generally the auditory canal will be found filled with pus, which varies in color from pure white to brownish or bloody, marked fetor always pointing to the existence of bone disease or to the presence of cholesteatoma. Lack of fetor may be taken as an indication that the chronic inflammation is confined to the soft tissues or is due to the absence of putrefactive bacteria. The appearance of the intratympanic mucosa varies considerably in color. It will be found red and swollen, having an edematous appearance, often with polypoid or granular excrescences. Large areas of extensive sclerosis are found in some cases. By means of a small, properly curved silver probe introduced the necrosis may often be made out.

Prognosis.—The prognosis of this disease depends upon the extent of the necrotic process, the physical condition of the patient, and largely upon the methods of treatment employed for its relief. In uncomplicated cases with the absence of bone necrosis and cholesteatoma, especially when the nasopharyngeal obstructions and diseases can be relieved by local operative interference and with modern methods of local treatment directed to the disease, the prognosis should not be considered unfavorable. Many such cases terminate in recovery, although traces of the disease may remain in the form of tympanic scars, dryness, perforations, sclerotic changes, and calcareous deposits in the membrane, and also varying degrees of deafness. Whenever any considerable degree of bone necrosis is found the prognosis must be considered less favorable on account of the difficulties present in the way of treatment, and because of the tendency to extension of the necrotic process to nearby and often vital structures. While the proportion of chronic purulent cases which at some period of life develop some serious intracranial or lateral sinus complications is not large, they do occur and they may occur in any given case.

This affection should never be considered lightly, neither should it be allowed to progress unattended by painstaking and persistent efforts to eradicate the disease process, or at least to minimize its activity. The prognosis is unfavorably influenced by granulations and polypoid masses. These usually protrude from the attic region and are indications of necrosis which may extend to the mastoid antrum.

Treatment.—In the foregoing remarks I have attempted to place before you the various phases of chronic purulent otitis media. Briefly stated, in chronic purulent otitis media we have a persistent intratympanic otorrhea with necrosis of either the lining membranes or the bony walls, in close proximity to structures so vital that should the infective process reach them a fatal termination becomes imminent. Before discussing the methods of treatment I desire to suggest the following: "What would the average physician recommend for a similar condition occurring in other portions of the body, for instance, about the hip-joint, in some one of the long bones, the pleural cavity, a chronic abscess about the appendix, or one in the pelvic region involving the uterine appendages?" Surely such patients would not be given the advice which is so often reported from patients who consult me, especially in out-door clinics: "My doctor told me to do nothing for the discharge from my child's ear, for if I did it would break out in some other part of his body." "My physician's advice was not to treat the chronic aural discharge, that it would disappear as soon as the permanent teeth appeared." "My doctor has told me that it would be a great mistake to have my child's tonsils and adenoids removed." On the contrary the patient would be advised to submit to surgical treatment, to be persisted in until cured. The ear should be no exception to the general rule that bone necrosis and pus discharge from any part of the human body offer a menace to health and often to life, and that the safety of the individual requires prompt relief and generally at the hands of the surgeon.

No treatment should be attempted until the most careful and painstaking efforts have been made to discover the exact conditions present, such examination to involve a thorough knowledge of the patient's general condition, whether or not organic disease is present, and of the state of the nose and nasopharynx, and a careful search as to the presence of necrosed bone, the condition of the ossicles, the presence of granulation tissue in the walls of the tympanic cavity or its proliferation through the perforation into the external auditory canal. In other words, the diagnosis should be made with great care, for upon it must be based the form of treatment which is to be instituted.

The treatment may be classified under three general heads, depending upon the location and extent of the disease: (1) Local measures; (2) intratympanic operation; (3) the so-called radical operation, the present status of which I shall endeavor to set before you clearly in the remaining portion of this address.

Of the three methods the simplest is that known as local treatment. This is applicable to and usually successful in a considerable proportion of cases of chronic otorrhea. The type of cases amenable to local treatment may be defined as the simple variety, wherein the soft tissues only are involved, or where

the bone necrosis is localized, and in those where the disease is aggravated by adenoids, hypertrophied tonsils, lack of cleanliness, proper nourishment and hygienic surroundings. Here the removal of diseased tonsils and adenoids, the establishment of right habits and methods of living, internal treatment with tonics and local treatment by modern methods will usually effect a cure. Primarily the local treatment should aim to remove accumulations of pus from the tympanic cavity and external auditory canal and to promote the rapid drainage of pus. In order to facilitate the flow of pus it may become necessary to remove or otherwise destroy masses of granulations or to enlarge the perforation. Obstructing polyps or granulations should be immediately removed. When of sufficient size a small snare may be employed, otherwise the most effective method is to fuse a small crystal of chromic acid upon the end of a probe and plunge it into the granulation mass.

Methods of Douching.—The cleansing of the purulent cavity by means of the douche or syringe is best accomplished by the employment of sterile normal salt solution. If large masses of dried secretion are found clinging to the walls of the cavity their removal is facilitated by previous instillation of a few drops of dilute hydrogen peroxide. If necrosis is present sterile bichloride solution, varying in strength according to the age of the patient, may be employed. These solutions should be warm, the temperature varying from 100° to 110° F. From one to two quarts of such solution in a fountain syringe, hung high up in order to give sufficient force to the stream, will serve to wash out the external auditory canal, and, when large perforations are present, the tympanic cavity. The return flow tip facilitates douching.

It is often necessary to irrigate the tympanic cavity and attic and this can be accomplished by using a slender glass or metal cannula slightly curved upward at the tip and carried well through the perforation. A more effective douche method has recently been devised by Dr. E. P. Fowler, one of my assistants at the Manhattan Eye, Ear, and Throat Hospital, by which the douche is so arranged that suction as well as douching is accomplished.

After douching there usually remain shreds of mucus or pus, and other active detritus which must be carefully wiped away with the cotton probe. Any needed intratympanic application may now be made. The success of this method of treatment depends largely upon the frequency and thoroughness with which local therapeutic measures are employed. If granulations recur applications of absolute alcohol or strong solution of nitrate of silver produce favorable results. Small areas of necrosis should receive frequent applications of nitrate of silver or iodine until the necrotic areas slough away. This treatment cannot be fully trusted to the mother and rarely even to the nurse, but the physician himself must not only examine the ear but also personally administer the local treatment almost daily for long periods of time.

At each sitting, in addition to ordinary douching, a careful otoscopic examination should be made and all remains of pus and detritus carefully wiped away. Inflation in chronic cases is often beneficial, the air douche forcing retained secretions from the Eustachian tube into the tympanic cavity. In the majority of cases it is advisable to continue the local measures above described for a considerable period of time, even for months, providing any reasonable measure of improvement warrants delay in operative procedures. The results obtained prove the merits of the method, as considerably more than fifty per cent. of all cases are cured or at least sufficiently improved to practically remove the dangers attending the chronic purulent process. Unfortunately the local measures prove insufficient when extensive necrosis exists, and some form of operative treatment must be instituted in order to eradicate the disease.

Two general methods of operation are valuable, either one of which must be decided upon according to the exigencies of the case. The first and simpler operation is the intratympanic, which is performed through the external auditory canal. This operation is also termed ossiculectomy. The second is the so-called radical operation, which is performed externally by the postauricular route.

The intratympanic operation or ossiculectomy is simpler in technique, avoids external incision, deformity, and prolonged and painful dressings. While it requires much skill and an accurate knowledge of the anatomical surroundings, it is much less formidable than the radical operation. It is necessarily limited in scope to the membrana tympani, soft tissues of the tympanic cavity proper, the ossicles, tympanic ring, and walls. Nevertheless, it is worthy of trial in cases where it can be fairly accurately demonstrated that the necrosis is confined to these locations. An ossiculectomy skilfully performed, with the curettage of all necrosed areas within reach, will in a somewhat limited percentage of cases effect a cure, and even when a complete cure is not effected the removal of the membrana tympani and ossicles opens a wide channel for the flow of pus from the deeper structures. It is a well known surgical axiom that large openings into pus cavities materially aid nature's efforts at repair.

I have repatedly succeeded in putting an end to a suppurative process in the middle ear by resorting to this method of treatment. It is somewhat difficult to define the class of cases in which it may be employed with a reasonable hope of success on account of the obstacles in the way of positively determining whether the necrotic process is confined to areas within reach; and yet the history, the amount and character of the discharge, and the intelligent use of the probe become valuable adjuvants in deciding whether or not ossiculectomy is indicated. All patients when advised to submit to this operation should be informed that it may fail to cure and that the more radical operation may subsequently become necessary.

The technique of the intratympanic operation does not properly come under the title of this paper, and enough has been said to indicate both its extent and its limitations. It is less hazardous to the patient, requires less after-treatment, besides being a procedure to which patients submit more readily than to the radical operation. Some elements of danger attend this operation, inasmuch as the necrotic process may have extended to the facial canal or to the labyrinth in some portion of its ramification. Facial paralysis, therefore, that bugbear of all operations upon the ear, may result. Again the forcible removal of granulations which may have their attachment to the exposed dura over the tegumen may open the way for meningeal infection.

These details have been introduced in order that the merits of the intratympanic operation may be compared with those of the radical.

For several years past the radical operation for chronic purulent otitis media has tended to supersede all other measures. Briefly stated, the purpose

of the operation is to convert the external auditory canal, tympanic cavity, attic, aditus ad antrum, mastoid antrum, and, if necessary, the mastoid cells, into one wide open cavity, eviscerating all granulations and diseased bone, destroying all membranous and muscular tissues, including the membrana tympani, and effecting dermatization throughout in the hope that by so doing the ramifications of the disease will be terminated once and for all.

The operation is a capital one requiring extensive dissection in the most complicated bone in the human body. Lying in close proximity to or imbedded in the structure are the cerebrum, cerebellum, lateral sinus with its ramifications, the internal carotid artery, and the facial nerve. These are among the reasons why it requires the utmost skill and a minute knowledge of the anatomy of the entire locality.

While the operation is extensive the disease is no less so, a fact which is fully proven by the percentage of failures to eradicate entirely the diseased area. Expert knowledge as to the management of venous, labyrinthine, and intracranial complications is also requisite, for at any time these complications may appear. The operation was first described by Küster, with modifications by Stäcke, von Bergmann, and others. American operators almost invariably clean out the entire mastoid cavity in addition to the specific radical work required to take down the separating walls of the various cavities.

The usual mastoid operation is first performed with a posterior incision, retraction of the soft tissues, chiseling through the cortex of the mastoid process, and excavation of the diseased areas in this neighborhood. In order to complete the radical operation a further resection is necessary of that portion of bone constituting the posterosuperior canal wall from the mastoid antrum forward to the tympanum, together with the roof of the external auditory canal, thus exposing the internal wall of the aditus ad antrum and removing the outer wall of the tympanic attic. In order to accomplish this the membranous canal is pulled forward. The malleus and incus are then separated and extracted, but the stapes should, if possible, be allowed to remain, except in cases where the purulent process has entered the labyrinth. With a curette the remaining portions of the drum, the entire lining of the tympanic cavity, and a large section of the posterior canal wall are cut away, leaving a large opening between the mastoid and the middle ear. With a small sharp curette the Eustachian attachment of the tensor tympani muscle is scraped away, with any granulations present, in an attempt to close off the Eustachian tube. After washing out the remaining cavity, if the operation has been thoroughly performed, the entire area will be bony. A flap is then made of the membranous canal in order to prevent subsequent atresia, and at the same time to favor the dermatization of the area. Some operators introduce skin grafts for this purpose. The posterior wound is then closed and the entire cavity packed with gauze—the packing being introduced through the enlarged external meatus. This completes the operation, the after-treatment of which is of great importance. All cleanly measures must be persisted in and exuberent granulations kept away until dermatization is complete, which in successful cases requires from three to ten weeks.

My fellow otologists will note that no attempt has here been made to describe the operation minutely, but simply in a general way to outline its nature and extent. This then is the operation which for the past ten years has been performed almost innumerable times in all the large cities of America, and with varying results. I shall now speak of the dangers attending the radical operation.

The first of these is the danger of injury to the facial nerve. If it can be determined that the facial nerve has a healthy bony covering throughout its course, one may curette with comparative safety, but often in cases of extensive necrosis, when the external wall of the facial canal is involved, it is extremely difficult to curette sufficiently to remove all diseased bone and at the same time protect the exposed nerve. Blood and granulation tissue obscure the view, and only by keeping before one the landmarks and course of the nerve is it possible to prevent injury. The anesthetist should watch the patient's face during dissection about the facial canal and warn the operator whenever the eye twitches.

The necrotic process will occasionally be found to have involved some portion of the labyrinth which adds a new danger to the operation, on account of the direct pathway to the brain which has become opened up to infection. It is often necessary that the necrosed bone in the labyrinth be eviscerated, even though this is attended with the danger of producing unpleasant after-symptoms. The majority of individuals suffering from purulent labyrinthinitis probably eventually succumb to the disease, unless by some good fortune or by operation, wide open drainage into the tympanic cavity is afforded. It has always seemed to me that, at least in a small percentage of cases, the radical opening of the labyrinth hastens rather than retards the fatal issue.

A third danger is found where an old undiscovered encapsulated cerebral abscess is stirred into renewed activity as a result of instrumentation during the operation. One such case happened in my practice and has been duly reported. The patient was a school boy, aged about eighteen, who was nearly six feet tall, weighed 190 pounds, and was a fine specimen physically. He had a profuse discharge of malodorous pus from the external auditory canal which did not lessen after three months of local treatment. The radical operation was therefore performed and I found the cortex so thick and hard that with the Rongeur forceps we could make no impression upon it and it was necessary to use the mallet and chisel throughout the operation. The attic tegmen was entirely necrosed and there was much necrotic tissue in the attic. The probe was passed up to the dura which looked inflamed. There was a bead of pus upon its surface which reappeared after wiping away, and the probe passed directly into a large abscess in the brain. I removed a large surface of bone over the temporosphenoidal lobe, and evacuated about two ounces of very fetid pus. The cavity was carefully drained and a cigarette drain introduced. The chiseling and other instrumentations probably had a bad effect upon the walls of the abscess, for in spite of every effort to prevent it, within two days the patient began to run a high temperature, acute meningitis developed, and he died in about ten days.

A fourth danger lies in the occasional injury to the dura, especially in unskilled hands, with a resultant meningitis.

We must add to the above enumerated dangers which occur in a very small percentage of cases, but nevertheless do occur, the further observation that even when thoroughly performed by the most skilful operators the percentage of complete cures (and by that I mean a permanent cessation of the purulent discharge) is not more than about 65. Many of the remaining have but intermittent discharge or are victims of reinfection, others throw off cholesteatomatous masses, and still others are

victims of further extension of the necrotic process. These results and statistics are gradually accumulating from published reports, and the end results are less rosy than the first enthusiasm seemed to imply.

On the other hand there are many favorable things to be said. One great benefit accrues even in cases where the discharge continues, and that is wide open drainage, which favors final healing, lessens the tendency to extension of the disease, and also lessens the dangers of serious complications. With these comments and figures before us the questions arise: "Is the operation justified?" and "Has it come to stay?"

I desire to be classed among those who believe that the operation is justified and necessary in a limited proportion of cases of chronic purulent otitis media. The enthusiasm for the new operation has made the pendulum swing too far, and from the more recent publications of our American otologists it would seem that the consensus of opinion about coincides with that which I have now expressed. I shall now attempt to describe the indications which seem to me to make justifiable the radical operation.

The radical operation is indicated: (1) When a permanent cessation of the purulent process has not been effected by prolonged local intratympanic treatment, combined if necessary with such minor operation as removal of granulations, enlarging perforation, etc. (2) When the cure has not been effected by the removal of necrosed ossicles and the curettage of the middle ear. (3) When acute symptoms of mastoiditis are present. (4) When a sudden cessation of the pus discharge produces vertigo, pain, or other unusual symptoms. (5) The appearance of facial paralysis during the course of chronic purulent otitis media. (6) Attacks of vertigo, indicating that the necrotic process involves the labyrinth. (7) In all cases where intracranial or lateral sinus involvement has already appeared. (8) Where there are positive symptoms of cholesteatoma in the mastoid antrum. (9) Where there are fistulous openings in the cortex of the mastoid process or in the osseous canal wall. (10) Whenever extreme depression or other symptoms of disturbed mentality accompany the disease.

The operation is contraindicated: (1) When the purulent process is tuberculous and accompanied by advanced general tuberculosis. (2) In advanced pernicious anemia or albuminuria and in cachectic diabetes. (3) It is usually contraindicated in young children. (4) In all cases where the disease is confined to the ossicles and tympanic cavity. (5) In adults who have scanty otorrhea without odor, with improper opening of the drum membrane, behind which are retained masses of secretion. (6) In all cases where it is possible to effect a cure by any of the other methods described.

It will be thus seen that the percentage of cases which should be subjected to the radical operation is not large, and in actual practice the statement holds true. It is also true that during the past five years too little discrimination has been employed in the selection of suitable cases for the operation. This should in no wise lead us to belittle this most important surgical procedure, for when properly performed in severe and dangerous cases of chronic otitis media it is the only safe and life-saving procedure known to surgery.

The question naturally arises as to how long local measures should be employed in chronic cases before being abandoned for the radical operation. What may be considered a reasonable length of time for such treatment? It is impossible to establish rules that will hold good for all cases, on account of the extreme variations in the character of the disease in different individuals. The general condition of the patient, his freedom from underlying organic diseases, the absence of odor or serious symptoms when free drainage exists, should lead one to persist in local treatment, especially when even a small degree of improvement attends the effort. In the simpler cases such treatment should be persisted in for from one to six months before attempting operative interference, during which time all efforts by both local treatment and internal medication should be employed. If local measures finally fail, then the question of the form of operation must be decided upon. In every instance when it may be fairly demonstrated that the necrosed area is confined to the ossicles, tympanic ring, and even the attic, the intratympanic operation should be performed, even though it may finally become necessary to resort to the radical procedure. There are certain cases in which radical operation should be performed without resort to preliminary local measures or ossiculectomy. Acute mastoiditis developing in a chronic purulent ear is an indication for immediate operation without delay of any kind. Continuous and excessive malodorous discharge, with extensive granulations, with or without cholesteatoma, is an indication for immediate radical operation. Symptoms of intracranial or lateral sinus involvement call for immediate operation.

My reasons for advising against performing the radical operation in young children are as follows: (1) The disease is rarely of sufficient extent to require it. (2) The disease usually yields to local treatment providing diseased adenoids and tonsils are removed. (3) By establishing free drainage, through a large perforation, with well maintained local treatment, a cure usually results. (4) It is better to place reliance upon these measures, aided by the marvelous recuperative powers of youth than partially or wholly to destroy his functions of hearing with all its train of misfortunes to happiness, education, the enjoyment of sounds, musical and otherwise, and finally to gaining a livelihood. I have always opposed performing double radical operations in children except to save life.

The radical operation is occasionally followed by fatal results, in the form of meningitis, sinus disease, brain abscess, and pneumonia; these do not occur as the direct result of the operation itself, but inasmuch as they follow soon after it is difficult to dissociate such occurrences in the mind of the laity. I have reported two such cases before the American Otological Society, and in the discussion that followed several members reported similar experiences.

These views represent my convictions as to the position which should be given to the radical operation in the realm of modern Otology, and it is hoped that they are neither too conservative nor too radical to meet with your approbation and approval.

HYDROTHERAPY IN THE TREATMENT OF THE INSANE.

By GEO. STOCKTON, M.D.,

COLUMBUS, OHIO.

SUPERINTENDENT COLUMBUS STATE HOSPITAL; PROFESSOR MENTAL DISEASES, STARLING, OHIO, MEDICAL COLLEGE.

In taking for my subject hydrotherapy in the treatment of insanity, I am aware that I have assumed a considerable contract, especially in the limited time at my disposal. I can only hope to touch on some of the most salient points. I am more particularly

interested in reading this paper for the purpose if possible of encouraging discussion, that we may be able to glean new ideas which may be useful to us in adding to our apparatus and technique.

It is only a few years ago that a well-known author, writing on the subject of hydrotherapy, made this statement: "Although vast strides have been made in the development and use of hydrotherapy in the treatment of nervous and mental diseases, but few State institutions in this country are supplied with the proper apparatus for using this most valuable adjunct to rational therapeutics." There is no doubt that the value of this method of treatment of nervous and mental diseases is being more appreciated every day. Many of the State institutions in various parts of the country have hydrotherapy outfits. In Ohio a number of our institutions have excellent facilities, and others are installing them. For a number of years the value of hydrotherapy has been realized abroad, some of the German universities give special courses in Physical Therapeutics, and considerable time is devoted to the teaching of hydrotherapy.

Too much attention cannot be paid to treatment in our institutions for the insane. Of what value is a brilliant diagnosis if nothing is done to improve the welfare of our patients or if we do not use every effort to bring about a cure? Why cannot we expect that remedies may be discovered and methods devised that will relieve, and, yes, cure many of these unfortunates? Whenever an institution is run merely for the custodial care of the insane, and no effort made to study and classify cases, it does not rise above the dignity of an infirmary.

We all know the value of fresh air and sunshine in the treatment of tuberculosis and other debilitating diseases. The use of water as a cleansing agent and as a therapeutic adjunct is along similar lines.

One great drawback to the advancement of hydrotherapy is that for many years it has been almost the exclusive property of the quack. Such individuals started institutions largely for commercial reasons, and this most valuable remedy was in most instances used without discrimination or method. Is it to be wondered that physicians looked askance at the so-called water cures, where many lives were no doubt endangered by the ignorant application of this remedy? The medical profession is broad enough to take advantage of any agent used logically that can be applied to the cure of disease. Osteopathy, so called, is massage applied in a certain way. Christian Science is suggestion applied in such a way that it influences the minds of susceptible people with fanatical religious proclivities, and very often individuals who are not of a very high mental organization.

It is a deplorable fact that many people are careless in regard to cleansing the body, and do not realize the importance of this remedy in enabling the system to resist disease. The story is told of a physician who recommended baths to a patient, and was astonished to get this reply: "Well, doctor, I don't know as it would make any difference, yet there has not been a drop of water on my body for twenty years."

It is believed by most people that hydrotherapeutic measures can best be administered in hospitals and institutions especially fitted with apparatus for the purpose; modern plumbing, however, has made it possible to have a very fair outfit in private houses.

Hydrotherapy applies not only to the external use of water, but to water taken internally, in which way it is used for cleansing certain accessible organs of the body. It is almost a universal rule with us in the treatment of melancholia, especially the agitated form, to wash out the stomach. Many of the cases come to our institutions in a miserable condition; emaciated, tongue heavily coated, breath offensive, sordes on the teeth, etc. We find similar symptoms, as you well know, in other forms of insanity, particularly in mania, and in some forms of dementia præcox. In many instances the stomach becomes so sensitive that it will retain nothing, and the patient on account of negativism or certain delusions, absolutely refuses to take food. By introducing the stomach or nasal tube, the stomach can be washed out thoroughly with some disinfectant solution, and the operation can be repeated as often as necessary; we shall then soon be able to introduce small portions of nourishing food, and in a very short time it will be retained by the stomach without much difficulty; the mucous membrane assumes a more healthy tone, the appetite returns, and the patient is soon well on to improvement and very often recovery.

Hydrotherapy to-day is largely administered on a physiological basis. Water exercises a very important influence over the circulation, the respiratory organs, and the nervous system, also a pronounced effect on the blood pressure. It may be stated in a general way that cold applications raise the blood pressure, and warm applications lower it. We all know how readily the action of the heart is influenced by the application of warmth and cold. The warm bath increases the rapidity of the pulse, which persists for some time after the bath.

Almost every organ in the body is in reflex relation to the adjacent skin, and many with remote portions; this is the rationale of the application of counterirritants, poultices, etc.

Among the laity such savory and odorous articles are used as coal oil, onions, etc. Fortunately, such agents are rapidly going out of favor, for up-to-date physicians know that the same effects can be accomplished through the application of heat and cold, by means of compresses wrung out of water at a proper temperature, with electric pads and other appliances.

Among the effects obtainable by water may be mentioned the following: Tonic, sedative, eliminative, diuretic, expectorant, antipyretic, antiphlogistic, hemostatic, hemagogic, analgesic, vasodilator, constrictive, etc.

A single energetic hot bath leads to the loss of a considerable amount of perspiration. We know that this diaphoresis influences the circulation of the blood and lymph, and morbid products are eliminated. This is the great desideratum and a most valuable remedy in certain forms of disease. Poisons may thus be eliminated, such as mercury and lead, bacterial toxins and pathogenic microorganisms also.

Neurasthenia is closely allied to insanity, indeed some authors classify it as a psychosis; the importance of hydrotherapy in the treatment of this disease cannot be overestimated. M. Beni Bardae, the French author, recommends hydrotherapy in the treatment of neurasthenia as follows: "Begin with a spray bath at from 92° to 99° F. The spray should be applied for some time along the spinal axis, but care must be exercised to guard against sudden shock, and one should endeavor to dispose the patient toward sleep. The douche should last from four to eight minutes, if it lasts much longer the patient is liable to be excited rather than soothed. The back is first sprayed, then the anterior surface, finally the limbs. Two baths a day should be given until the nervous agitation ceases. This may take a considerable period of time to stimulate the or-

ganism. The temperature of the water may be reduced gradually during the process of the bath. Any tendency toward reaction may be relieved with hot water. If the heart is affected, only the lightest application of a stream of water over the chest is allowable."

In the treatment of neurasthenia we have found that various forms of baths have to be used to fit individual cases; the conditions change frequently and the treatment must be applied acordingly. Electric light baths, followed by gradual cooling, usually leave a feeling of well being. Neutral baths which are administered at about the normal temperature of the body are very valuable. If the patient suffers greatly from insomnia the baths should be given at night. Many in this class of cases improve under hydriatic treatment when we have had absolutely no benefit from drugs. These patients should be impressed with the fact that results cannot be obtained at once, and sometimes weeks elapse before anything seems to have been accomplished.

In our outfit we have the Turkish and Russian bath, electric light cabinet, sitz, perineal spray, foot bath, local electric light appliances constructed so they can be used on various parts of the body for the purpose of producing localized hyperemia, massage tables, wet and dry shampoo tables, electric bath and distributing outfit bearing upon the apparatus for needle shower baths, etc. One great objection to the use of bathrooms is the stale odor which permeates the atmosphere, especially when they are crowded and heated with steampipes. We are able to overcome this by having a large fan run by an electric motor; connecting with the room in which the fan is located is a large duct made from sewer pipe. From an opening in the floor of each separate bathroom, a small duct extends to the large one. When the fan is running the vitiated air is being constantly pumped out and the rooms are more pleasant and habitable.

The care of the chronic and infirm class is much easier and more satisfactory by having proper bathing facilities within easy access; the stimulating and cleansing effect minimizes the development of bed sores, the exhalations of the body are not so offensive, and the patient is more contented and happier.

One enthusiastic author writes that instead of isolating the chronic insane, he manages them in open wards through the systematic use of prolonged baths and packs. At first the patients were kept in the bath at a temperature of 98° to 100° F., from one-half to three or four hours; later, in some cases, the time was extended to from twelve to fourteen hours. He claims that the patients not only improved, gained in weight, slept better, and became quieter, but that they were also able to dispense with the use of drugs.

I doubt if it is advisable for everyone to take the cold bath, unless the person is very vigorous and the bath is followed by energetic rubbing. Water when too cold, applied unexpectedly to a large surface of the body, produces a severe shock, and care should be used in its application. At the proper temperature, and adapted to the individual, it adds to the nervous energy, stimulates the functions of the body, and improves the person's resisting power against disease. The kidneys act more vigorously, the fact that the urine is found to be more toxic after a bath is abundant proof that baths assist in the elimination of poisonous material. It stimulates respiration and so eliminates poisonous matter. The use of baths in no way interferes with the medical treatment of patients, and indeed, properly administered, they largely increase the efficiency of many drugs and do not interfere with any. The warm bath renders the surface of the body less sensitive, numbs the terminal nerve fibers, and produces a sedative action. Whenever there are delirium, restlessness, and insomnia, the neutral bath is indicated.

At Morris Plains it was found that a wet pack or full bath at from 95° to 105° F. was very useful in excited cases of insomnia. In some cases of mild excitement with confusion, the use of the wet pack will often assist to restore the normal condition.

Baker reports the employment of hydrotherapy in 26 cases of melancholia, with or without agitation, dementia præcox, hysteria, puerperal insanity characterized by slowness of thought, painful delusions, etc., cases showing lack of nervous and muscular tone, sluggish circulation, loss of weight, greasy and acne-covered skin, intestinal fermentation, and other complications. The baths in these cases are used for various periods, depending of course on the case; he reports decidedly good results, such as quieting of agitation, gradual disappearance of delusions, and physical improvement. He sums up his results by saying that hydriatic measures are valuable adjuncts to hygienic and medicinal measures.

In our own outfit we get good results from the wet pack. A sheet is wrung out of cold water and placed on a table prepared first with a rubber sheet and blanket. The patient is placed on the couch and the sheet is pulled over the body, the blanket is then brought up on both sides and tucked in around the person; a cold compress to the head and warm applications to the feet are proper; straps may be used to confine the patient to the table if needed. In many cases the patient quiets down and sometimes goes to sleep in the pack.

We use baths in almost all forms of insanity. To produce elimination we usually prefer the electric light cabinet. In many instances disturbed patients will become frightened and resistant if placed in a Turkish or Russian bath. The patient remains in the bath until in a profuse perspiration, and is then placed on a table and washed with water at about 102° to 105° F., and given what is known as a Swedish shampoo. After being thoroughly rubbed with soap, the patient is put in the rain bath, and the spray used at a temperature of from 100° to 102° F., and after being allowed to cool off gradually in the rest room, is through for the day.

Our operators find the neutral bath and pack of great value in the treatment of cases of mild excitement and restlessness accompanied by insomnia. A sheet is wrung out of water anywhere from 93° to 97° F., the patient is enveloped in this and then wrapped in a light blanket; this sheet fits so closely to the body that it is really a mild form of restraint. The neutral bath is administered in a large bathtub, which completely submerges the patient; he can be kept in this as long as is deemed necessary. We tried the continuous bath in one case. The patient was in the bath about three weeks continuously. For a time she seemed to improve, but she had a relapse and we were obliged to discontinue the treatment on account of lack of room. We are, however, so favorably impressed with the method that we are arranging to equip two rooms for the purpose of employing it.

The salt glow is a favorable procedure with our woman operator; she takes a salt known as butter salt and places it in water at about 60° F., then applies the mixture freely to the back and chest, then the arms and limbs, rubbing vigorously; the spray and douche are then applied the same as after a Swedish shampoo.

In my opinion hydrotherapy cannot be properly

applied unless the physician has skilled operators to carry out his directions. While as a rule a medical man should have general supervision, and should be capable of prescribing certain baths indicated in various forms of insanity, nevertheless a great deal of latitude should be allowed to those who administer the treatment. A physician cannot always foresee the effect of different kinds of baths on the individual any more than he can predict in all cases the action of certain medicines. Bath attendants who understand their work soon learn to recognize unfavorable symptoms when they arise, and are prepared in many instances to meet emergencies.

In preparing this paper I have drawn from numerous sources for information. I will not attempt to enumerate all. I am especially indebted to Baruch's work on hydrotherapy, to articles by the late Dr. Dent, and by officials connected with Morris Plains State Hospital.

A CONTRIBUTION TO THE STUDY OF THE DIATHETIC STATES.

By C. T. NESBITT, M.D.,

WILMINGTON, N. C.

Extended inquiry has led me to the conclusion that the diatheses make possible the establishment of the great majority of diseased conditions in which there is progressive structural degeneration. If this be true, it is reasonable to assume that it is possible to determine the relationship existing between these depraved nutritional states and the various diseases, and to prevent the development of such diseases by careful management of the very young diathetics.

Every civilized individual has inherited some depraved nutritional tendencies. The majority are so profoundly affected that the stress of modern life, together with the effects of infection, dissipation, and injury, make their premature destruction inevitable. If it is possible to correct these nutritional faults while the individual is in the formative period, it is the plain duty of every physician to study the heredity of every child in his clientèle, and to see that each has the best opportunity to attain his highest usefulness and greatest longevity.

In presenting these cases I am aware that they are too few to be considered conclusive, yet certain tendencies are exhibited in the development of disease, which I hope will lead others who are more capable, and who have greater opportunities for research to continue the collection of case histories.

The classification of Bouchard, who divides the diathetic states under two heads, viz., scrofulosis and arthritism, seems the most convenient for the purpose of this inquiry. Each of these states is defined with sufficient clearness to enable the investigator to arrive at a reasonably sure conclusion with reference to the state of an individual, from the information obtainable from an intelligent person who knew the object of inquiry intimately. Height, weight, color of hair, eyes, habits, temperament, illnesses, time and cause of death, and all other obtainable data, will be in many instances sufficient to enable the careful investigator to determine accurately the nutritional state of those progenitors whom he cannot examine. This has been the course I have pursued in collecting the cases presented herewith. No cases have been included in which I could not reasonably establish the health state in a majority of the individual progenitors. Those classed as arthritics gave definite histories of gout, chronic rheumatism, asthma, obesity, Bright's disease, diabetes, etc., and displayed in their personal histories the stigmata of the arthritic state. Those classed as scrofulous gave definite histories of scrofuloderma, tardy development, etc., and showed positive indication of the status lymphaticus. I am aware that this classification is open to grave criticism; yet long study of those states leads me to believe the determinations reasonably positive.

Cancer.—Of the cases of malignant neoplasm, the eight first recorded were so-called sarcomata in the very young. It will be noted that cases 2, 3, 4, and 6 had cancerous grandparents, and that in case 4, the paternal and grand paternal grandmothers were both cancerous. The transmission in this case being from mother to daughter, and through the son to his daughter, if there was transmission. Case 7 shows but one cancerous progenitor. The remaining thirty-nine cases were adults between the ages of thirty-three and sixty-two. Twenty-two cases were operated upon, sixteen suffered further malignant development through metastases; six died shortly after operation; the remaining seventeen died without operation. In all of the forty-seven cases the malignancy was the acknowledged cause of death.

Reference to the chart will show that out of the forty-seven cases, sixteen had cancerous progenitors. Twenty-one cases, including those just mentioned, gave a history of cancer in the collateral branches of the family. Thirty-eight of the forty-seven cases occurred in individuals who were the result of procreation between two persons, one of whom was definitely arthritic, and the other as definitely scrofulous. In sixteen cases there were three arthritics and three scrofulous each in the six immediate progenitors. In eleven cases there were two arthritics and four scrofulous, in five cases there was one arthritic and five scrofulous, and in only two cases (9 and 15) were there fewer scrofulous than arthritics. Both of these were cases of renal cancer in adults. Cases 20, 26, 28, and 40, in which there were three arthritic, two scrofulous, and one cancerous ancestor, were also renal malignancies.

The conclusions that seem to be warranted by the histories of the heredity element of these cases are:

The development of malignant neoplasms is furthered, if not caused, by the admixture of the two diathetic states in procreation.

The preponderance of scrofulosis in the diathetic history is probably essential to the production of cancer.

The great majority of cancerous individuals are the result of procreation by two, one of whom is arthritic and the other scrofulous.

Transmission of diatheses is most often from father to daughter, and from mother to son, as has been determined with reference to other hereditary transmission.

Preponderance of arthritism over scrofulosis in the ancestry of an individual, is a possible factor in the production of renal cancer, when the individual has had a cancerous ancestor.

Diabetes Mellitus.—In collecting these cases of diabetes mellitus, the same method was pursued as in the preceding report. All were idiopathic and persistent.

The first five cases were in children whose ages at the time of record were as follows respectively: 5 yrs. 6 mos.; 5 yrs. 6 mos.; 6 yrs.; 6 yrs. 8 mos.; and 8 yrs. The remaining thirty-three cases were in adults, whose ages ranged from thirty-seven to

sixty. Two were less than forty, five less than fifty, and twenty-six less than sixty years old. These persons were all white, eighteen were Hebrews. Four of the five juvenile cases had diabetic ancestors. Three of the four had two diabetic progenitors. Case 6 had three, as will be noted.

Of the entire series, only thirteen cases had diabetic heredity. It will be noted that in one case (10) there was an instance of conjugal diabetes. The preponderance of arthritism in the histories presented is significant. Only three of the series had so few as three arthritic progenitors, and in nine cases all were of that diathesis. In the remaining cases arthritism predominates greatly. Scrofulosis appears in only six instances, and in these singly. Of the thirty-three adult cases, eighteen had one or more healthy progenitors. The letter x indicates that my inquiry developed nothing to indicate grave nutritional fault. In every case, however, the immediate parents were arthritic or diabetic.

The conclusions to be drawn are:

Diabetes mellitus is possibly the result of the transmission of the arthritic diathesis through several generations in which there has been little or no marital admixture of scrofulosis.

Scrofulosis is unimportant in the etiology of this disease.

The production of diabetes mellitus in the majority of instances depends upon the further development of nutritional fault that has been inherited.

Nephritis.—The cases of chronic nephritis herewith presented were investigated by the same method as pursued in the other reports.

Of the thirty-five cases, twenty-one, including the five juveniles, were of the parenchymatous, and the rest were of the interstitial type of Bright's disease. The five juvenile cases were the result of infection, two scarlet fever, one pneumonia, one diphtheria, and one measles.

Of the remaining thirty cases, none was subjected to the influence of the mineral poisons, excepting Case 17, who worked in a paint factory. Four of these were women, one of whom had parenchymatous nephritis, the others interstitial.

Of the entire series, fourteen inherited the tendency to nephritic disease from direct progenitors. Eleven of these progenitors had the interstitial type of nephritis, if such determination can be warranted by information obtained at second hand. I examined but one of these persons, the mother of Case 4.

The most important fact developed in the history of these cases, is the obvious influence of alcoholism in the production of chronic nephritis. Those progenitors designated as alcoholics were either steady drinkers or periodic drunkards. Moderate use of alcohol was not considered alcoholism. Not one of the series was free from alcoholism in some form in the family history. Eleven, including one female (Case 6), were themselves dipsomaniacs. Fourteen others were moderate drinkers, and ten, including three females and five juveniles, were abstainers.

In the entire series, thirty-one of the thirty-five cases had alcoholic heredity. Of the five juvenile cases, two had three alcoholics each, and three had two. Of the adult cases eleven had both alcoholic and nephritic heredity, and all these cases were of the parenchymatous type.

Scrofulosis is found in only four cases, two of which occurred in the great grandparents of juvenile cases. In Case 17, which shows two scrofulous ancestors, the individual was a paint mixer, and was also an alcoholic. This was parenchymatous in type, and terminated in uremic coma.

Arthritism is the basic etiological factor in these renal diseases, as indicated by the great predominance of this state of nutrition in the direct progenitors.

The conclusions to be drawn are:

Intensification of the arthritic diathesis through hereditary transmission is the most probable predisposing cause of chronic progressive renal degeneration.

Alcoholism in the ancestral and personal history of the individuals who are essentially arthritic, is the most important precipitating cause of chronic nephritis.

It is possible that alcoholism and renal disease combined in the heredity of an individual predispose to the parenchymatous type of nephritis.

The other etiological factors recognized in the production of chronic nephritis are secondary in importance, and contribute in a general way only to the development of the disease.

Scrofulosis is important in the etiology of nephritis as a remotely contributing factor.

In addition to the cases herewith presented, I have collected a number of cases of other depraved nutritional states, with the same object in view. I hope to report them at some future time.

If the conclusions are warrantable, efforts at prophylaxis must include the hygienic and dietetic management of the very young. My own experience along this line includes the management of a number of children of pronounced diathetic heredity, the majority of whom have shown marked decrease of the stigmata. It is of course true that none of them has had time to demonstrate the success of my treatment; but the benefit has been so pronounced and so lasting in such a majority of cases that I am to be excused for hoping that the continuance of the habits and mental states which I have founded will bring immunity from the long list of progressive degenerative diseases, and will greatly modify the transmission of the diathetic states to the progeny. There can be no doubt that the usefulness and happiness of these individuals will be greatly enhanced.

The field that promises most in results in this work lies in the great boys' schools of the country. Here the intelligent and conscientious medical advisor will find conditions that are nearly ideal for the work. Here he will have complete control of the boy at the time when the plasticity of both mind and body makes possible the implantation of physical and mental activities which will cling to him through life, and will insure to a great extent his development into potent manhood and healthful fatherhood.

CEPHALOCELE, WITH A REPORT OF THREE CASES IN ONE FAMILY.

By JOHN PHILLIPS, M.B.,

CLEVELAND, OHIO.

DEMONSTRATOR OF MEDICINE, WESTERN RESERVE UNIVERSITY; ATTENDING PHYSICIAN TO THE DISPENSARY OF THE BABIES' DISPENSARY AND HOSPITAL.

THE cases of cephalocele here reported are of unusual interest because of their occurrence in children of the same family.

Doris J., two months old, was brought to the Dispensary of the Babies' Dispensary and Hospital, February 10, 1908, for instruction in feeding. Her father, a Swede, had died two weeks previously from pneumonia. Her mother was of Irish descent and was in good health except that she had a slight cough. The parents had two other children, a boy six years old and a girl twenty-six months old, whose histories will be mentioned later. One child died five days after birth from unknown cause. There was no history of miscarriages. This baby weighed 6¼ pounds at birth. The labor was easy and the child appeared normal except for a small swelling in the nasofrontal region which increased in size when the child cried. This swelling has not changed. The mother nursed the child, and, with the exception of a mild conjunctivitis beginning three days after birth and lasting two weeks, the child has been in good health.

The baby was bright and active and weighed 3,795 grams. Her skin was clear except for a slight intertrigo in the napkin area. The head was of normal shape, except that the occiput markedly projected backwards. The posterior fontanelle was closed; the anterior measured 3 ¾ cm. In the median line in the nasofrontal region was

Spina Bifida Occulta.

a soft rounded swelling 2 cm. in diameter, which projected 1 cm. above the surface. It became larger and quite tense when the child cried. Pressure on the tumor diminished its size. Its lower border reached just to the root of the nose. A slight defect was felt in the bone by pressing deeply over the middle of the tumor. The circumference of the head was 39 cm. A few pea-sized glands were present in the post-cervical, axillary, and inguinal regions. The epitrochlear glands were palpable. The lungs and heart were normal. A small fungus umbilici was noted, otherwise nothing further was revealed on physical examination. The baby was seen on March 11, its weight being 4,153 grams, and again on April 27, weight 4,700 grams. The nasofrontal tumor has remained unchanged.

The second child Agnes J., twenty-six months old, was brought to the clinic because of weakness in her left leg. She weighed six pounds at birth. The labor was easy. Her mother nursed her until she was sixteen months old. She cut her first tooth at five months and walked at twenty-one months. She has not talked. For four months previously the mother had noticed a weakness in

the left leg, especially at the ankle, and that the foot would turn outwards when the child put her weight on it. At no time has the child had a serious illness. Since the birth the mother has noticed a swelling in the forehead just above the root of the nose. This swelling has remained the same size or has only slightly enlarged.

The child was undersized, its weight being 8,225 grams, and its musculature quite flabby. The head measured 45.5 cm. in circumference, the occiput projecting backward 4 cm. beyond the plane of the posterior part of the neck. The anterior fontanelle was still open 1 cm. In the median line in the frontal region extending for 3 cm. upwards from the root of the nose was a rounded swelling 2.5 cm. in breadth. This was soft, not reddened, and painless, becoming larger and more tense on crying. A slight defect was felt in the bone in the region of the swelling. The nose was broad and somewhat flattened. The child had sixteen teeth. The submaxillary glands were pea-sized; two bean-sized glands were felt in the left side of the neck just posterior to the middle of the sternomastoid muscle. The axillary, inguinal, and epitrochlear glands were palpable. A well marked rosary was noted in the examination of the chest. The lungs and heart were normal. The abdomen was large and the abdominal muscles quite flabby. At the lower part of the spine, 3 cm. above the tip of the coccyx, was a small dimple extending directly inwards 2 cm. and ending blindly. The child could walk, but there was an apparent weakness of the left ankle so that it turned outwards. The thighs measured the same, but there was a definite asymmetry in the two calves, the left measuring 14 cm., the right 14¾ c.m. The muscles of the left calf were quite flabby but gave no reaction of degeneration. The patellar reflex was normal. An attempt was made to test the body and extremities for sensation but no information could be elicited beyond the fact that tactile and pain sense were preserved.

The third child, a boy 6 years old, was brought to the clinic April 28 at our request. The mother said that he had a swelling of his forehead similar to that observed in the other children at the time of birth and that it disappeared gradually so that it had not been noticeable for two years. The boy was intelligent and no trace of the nasofrontal tumor could be made out, and no defects in the bone except a slight roughening of its surface. His head was large, measuring 53.5 cm. in circumference. The occiput was broad and projected 6 cm. backward beyond the plane of the posterior part of the neck, and the external occipital protuberance was large. There was nothing further of importance in the physical examination.

The extraordinary feature of these cases was the occurrence of nasofrontal cephalocele in three children of the same family. Ssamoylenko has reported two cases of nasofrontal meningocele in one family. In the second child the atrophy and weakness of the muscles of the left calf could be explained on the supposition that the defect in the spine has interfered with the root fibers of the cauda equina coming from the second sacral segment of the spinal cord. Another interesting feature was the very prominent occiput present in all the children.

Cephalocele is the term applied to the tumor resulting from the protrusion of the cranial contents through an opening in the skull due to a defect in development. Cephaloceles are classified according to their structure and contents as follows: (*a*) Meningocele when there is protrusion of the meninges alone, the sac being filled with cerebrospinal fluid; (*b*) Encephalocele when a portion of the brain itself protrudes into the sac; (*c*) Encephalocystocele when the tumor consists of a protrusion of a portion of both the brain and meninges, this protrusion being distended by a collection of fluid which communicates with the ventricles of the brain. Muscatello has divided all brain and cranial malformations into two categories. The first category, called acrania, includes defects of the entire cranial vault (holoacrania) or a part of the same (meroacrania). In these manformations either the entire brain is lacking or it is present and approaches the normal brain, but a part of the brain substance in the form of a hernia projects through the defect in the skull. This Muscatello calls exencephaly. The second category (encephalocystocele) includes those cases in which the hernia has escaped through a bone opening of narrowed dimensions, and includes inside the brain mass, as an extension of the brain ventricle, a cavity in which the fluid collects in varying amounts.

The most common situation of cephaloceles is in the anterior or posterior portions of the skull, the former being called sincipital cephaloceles, the latter occipital cephaloceles. Those of the latter variety are known, depending upon their position above or below the tentorium, as superior and inferior occipital cephaloceles. In the superior form the defect is in the median line just below the posterior fontanelle, and may communicate with the same. The defect in the inferior form is just above the foramen magnum and may communicate with it. In the sincipital variety the parts leave the cranium in the nasofrontal region, and Fenger has classified them as follows:

(1) The nasofrontal hernias leave the cranium between the frontal and nasal bones and form a tumor in the median line in the region of the glabella.

(2) The nasoethnoidal hernias leave the cranium between the frontal and nasal bones on the one side and the lateral mass or labyrinth on the other, which is forced or displaced downwards toward the nasal cavity. The tumor appears externally in the region of the border between the osseous and cartilaginous portions of the nose, hanging down toward the tip or the wing of the nose.

(3) The nasoorbital hernias leave the cranium between the frontal, ethmoid, and lacrymal bones. In the region of the latter they enter the orbit and present at or near the inner canthus of the eye.

Another interesting variety is the basal hernia, which is distinguished from the other sincipital hernias by not causing a protruding tumor in the face. Fenger, quoting Heinecke, gives three classes: (1) Cephalocele sphenopharyngea, the most common variety, leaves the cranium through an opening between the body of the sphenoid bone and the ethmoid bone, or through one of these bones, to come down in the nasal, nasopharyngeal, or buccal cavity. In Czerny's case the tumor presented in one of the nostrils; in the cases of Giraldès, Otto, Klimentowsky, and Fenger in the nasopharyngeal cavity; in the cases of Virchow, Lichtenberg, Klintosch, and Serres, cited by Larger, in the mouth through a cleft palate. (2) Cephalocele sphenoorbitalis, which leaves the cranium through the superior orbital fissure to enter the orbit behind the globe of the eye. (3) Cephalocele sphenomaxillaris leaves the cranium through the superior orbital fissure, but instead of remaining in the posterior part of the orbit, descends through the inferior orbital fissure into the sphenomaxillary

fossa. The tumor can be felt in the mouth on the median side of the ascending ramus of the inferior maxilla and is visible on the outside of the face, on the cheek below the zygoma.

The last two varieties Fenger says are very rare. In 93 cases of cephalocele Honel cited by Ruhräh found that 68 were occipital, 16 frontal, and 9 basal. Schatz, cited by the same author, in 105 cases gives 59 occipital and 46 frontal and does not mention the basal form. In 75 cases Laurence found 53 occipital. With rare exceptions the tumors are in the median line. The writer saw one case in a child seven months old where the hernia was situated in the lamboid suture 3 cm. to the right of the median line. This deformity is often associated with other malformations. Thus Laurence in his 75 cases found 16 in which there was spina bifida. In the second case of the series here reported there was a spina bifida occulta.

The size of cephaloceles varies greatly and depends upon the amount of cerebrospinal fluid that collects within the tumor. They may be so small that they escape observation, or again they may be larger than the head. In the large encephalocystoceles the brain substance becomes very thin. In cases where the opening in the cranial bones is small the tumor is pedunculated. If the opening is large the base of the tumor is correspondingly large.

Little is known in regard to the exact causes of these malformations. They occur about equally in the two sexes. Ruhräh found, in 39 cases where the sex was stated, 21 males and 18 females. H. Cushing states that the following hypotheses have been offered for their production: "That owing to some irregular division of the brain into its separate parts portions of the primitive brain vesicle come to lie outside the mesodermic coverings; that they are actual neoplasms—encephalomata (Berger); that they are brought about by the traction of amniotic strands which may have become adherent to the primitive nervous system." Cushing further states that the defect through which the protrusion takes place is not the primary factor leading to the hernia but rather that some intracranial condition leading to increased tension and associated in some way with the cerebrospinal fluid was present during fetal life. In support of this he mentions the fact that the cerebrospinal space forms and contains fluid before the lateral plates have totally enclosed the primitive nervous system, and in case there should be any increase in the amount of fluid or any obstruction to outflow by normal channels, it will tend to bulge the meninges through the areas where solid closure by the lateral plates is least advanced, and by so doing it will prevent such closure.

This condition usually produces no symptoms unless pressure is exerted on the tumor. Under such circumstances, especially in cases of encephalocele, there will be respiratory disturbances, slowing of the pulse, vomiting, convulsions, and sometimes unconsciousness. In meningocele the tumor is smooth, cyst-like in character, quite tense, nonpulsating, and can be reduced by pressure. Occasionally pressure will give the symptoms enumerated above. Sometimes the tumors are translucent and they become larger and more tense when the child cries. Only a slight if any defect can be found in the skull. In encephalocele the tumor is smooth, not translucent, and often pulsates. Pressure gives cerebral symptoms often associated with changes in the size of the pupils or strabismus. In encephalocele we have a large pedunculated tumor, which fluctuates but does not often pulsate. Cushing says that encephalocystoceles of the frontal region communicate with the anterior horn of the ventricle; those of the superior occipital region with the posterior horn; and those of the inferior occipital region usually with the third ventricle.

Various conditions must be taken into consideration in the differential diagnosis of cephalocele, viz., dermoid tumors, lipomata, sebaceous cysts, angiomata, sarcomata. A great aid is the fact that the lesions are congenital and that they are usually found in definite situations. The basal hernias which present in the nasopharyngeal space must be distinguished from nasal polypi.

The majority of these children die a short time after birth. In a few cases they may live to adult life or even to old age, but, unhappily, they are usually feeble minded. In those who survive for some time hydrocephalus is a common accompaniment of the lesion. Meningoceles usually increase steadily in size, while encephaloceles either remain stationary or the growth is very slow. Mitchell and Ronaldson, cited by Ruhräh, have reported cases of spontaneous recovery in cases of meningocele. Such was probably the case in the oldest child of this series.

Various measures have been advocated for the treatment of this condition, viz., pressure by bandage, the withdrawal of fluid from the sac, and the injection of irritating fluids such as Morton's into the sac, with the hope of causing oliterative adhesions. None of these methods gives favorable results. H. Cushing sums up the treatment as follows: "Operative measures alone can promise any permanent benefit, and even they may be futile if the hernia is accompanied by a large cranial defect through which the brain has prolapsed, by defective cerebral development, or by other congenital abnormalities. There remains a small group in which the operation is justifiable and its effect gratifying. A meningocele with a small pedicle may often be successfully removed, the opening closed, and no further symptoms result. The small encephalocele of the frontal or occipital origin may likewise be closed after amputating or reducing the cerebral protrusion and repairing the meningeal and cranial openings; if they are large, by a plastic operation of some sort. For the purpose of closing such a defect a flap of scalp or periosteum alone, or one of periosteum and bone, or one of all three coverings may be taken, leaving only the intact dura over the brain at the area from which the flap has been taken. As these operations are done on very young children, as a rule, the thin shell of bone may be easily cut in the desired form, its pedicle cracked off, and the fragment swung and sutured into position. The surgical technique must be of the very best, for a single point of weakness in the healing wound—a stitch abscess, for example—may lead to subsequent leakage, since there is a tendency toward a rapid reaccumulation of the fluid." Quite a number of cases have been operated on with good results in recent years. Fenger operated successfully in a case of basal hydrencephalocele simulating a nasal polypus.

TREATMENT OF SECONDARY ANEMIA OF TUBERCULOSIS WITH HYPODERMICS OF IRON.

By LEROY S. PETERS, M.D.,

SILVER CITY, NEW MEXICO.

PATHOLOGIST, NEW MEXICO COTTAGE SANATORIUM.

As years go by and we make further progress in the science of medicine, new ideas are born which make stepping stones to more rational methods of treatment, and which put the science of therapeutics on a firmer and stronger basis. The hypodermic injection of medicine is fast gaining ground, and bids to be by far the most sensible, if not the most perfect way of administering drugs in the future.

In the days of our forefathers the physician was content to carry his hypodermic syringe for cases of emergency. He used it to allay pain and to administer stimulants when he thought them needed. It was then returned to its case and tucked away to await another hurry call. To-day it is gaining a place in the armamentarium of the modern physician as common as the niche filled by the bottle of calomel pills carried by our ancestors.

It is my object in this paper to point out the results obtained by hypodermic injections of iron in forty-two cases of secondary anemia accompanying tuberculosis. For the past two years we have given all our iron by the hypodermic method, and our results have been so gratifying that we think them worthy of consideration. Before we began the use of iron hypodermics we gave the usual blood tonics, such as Blaud's pills or iron in some form or another, per os. We were never able to get results worth consideration inside of three months, while by the hypodermic method we can get the desired effect usually with twenty doses, given on twenty consecutive days.

In this institution, at an altitude of six thousand feet, anemia is relatively an insignificant factor in tuberculosis. In fact, the cases reported here are from our records extending over a period of two years, in which time we have treated over 150 tuberculous invalids.

The estimation of hemoglobin was made with a von Fleischl instrument, and the results recorded in the percentage of hemoglobin in 100 grams of blood.

In giving the pulmonary status of the patient we have followed Turban's classification, and indicated the degree of involvement by the Roman numerals I, II, III, corresponding roughly to incipient, moderately advanced, and far advanced cases.

The hemoglobin percentage is indicated both on admission and after treatment, as is also the number of injections required to produce the result.

We use a number of formulas of different combinations as follows:

1. Iron citrate	gm.	.05
2. Iron citrate	gm.	.05
Sodium arsenate		.005
Strychnine sulphate		.0005
3. Iron citrate		.05
Sodium arsenate		.001
4. Iron citrate		.05
Strychnine sulphate		.001

The citrate of iron is the one best suited for anemia alone. By using the preparation of iron, strychnine, and arsenic one gets the action of the iron plus the tonic effects of the arsenic and strychnine.

These preparations may be obtained in a fused glass vial ready for injection or they can be put up by one's own druggist. We prefer the fused vial because of the readiness with which it can be used. The top is snapped off, the needle inserted into the vial, and the fluid withdrawn. The syringe is thus filled and the injection made into the gluteal region after thoroughly cleansing the part with alcohol or some other disinfectant.

Case	Pulmonary Status	Hemoglobin on Admission	Hemoglobin After Treatment	Number of Injections Required
1	II	10.96	13.015	20
2	III	10.96	12.878	20
3	II	11.645	13.7	20
4	III	11.645	13.7	20
5	III	10.96	13.7	20
6	III	11.645	13.015	20
7	II	9.59	13.7	20
8	I	9.59	13.7	20
9	III	9.59	14.385	20
10	III	11.097	13.015	20
11	II	12.607	14.796	20
12	I	11.782	13.837	20
13	III	10.96	13.526	20
14	II	10.96	12.33	20
15	III	10.275	12.33	40
16	III	10.412	13.015	20
17	III	10.96	13.7	20
18	III	11.782	12.33	20
19	III	11.234	13.974	40
20	II	10.549	12.467	20
21	III	11.234	12.467	40
22	III	9.864	10.686	20 (died)
23	III	10.96	12.33	20
24	III	10.275	12.741	20
25	I	9.59	11.782	20
26	II	10.038	13.7	20
27	III	10.96	13.015	20
28	I	10.275	12.741	20
29	III	11.371	13.152	20
30	III	11.782	14.659	20
31	III	11.645	13.152	20
32	III	9.59	13.015	20
33	II	10.275	14.111	40
34	I	10.125	13.015	20
35	I	9.59	12.33	60
36	I	11.782	13.015	20
37	III	7.946	13.015	30
38	III	10.96	11.371	20
39	III	10.96	12.33	20
40	III	10.96	11.645	20
41	III	10.275	13.152	20
42	III	10.175	11.645	20

It will be seen from the accompanying table that in all cases treated good results were obtained, and that in nearly every case after twenty injections.

Of course the anemia is not marked, but nevertheless I have no doubt that the same good results could be obtained in more severe cases. It goes without saying that in anemias of more severe type a larger number of injections would be required.

It would be interesting to determine its value in the treatment of the primary anemias, or in any condition where iron is indicated. The number of cases (42) is too small upon which to base radical conclusions, but it seems to me that the method is rational, and one deserving wider and more general use.

The Inhalation of Oxygen to Prevent Nausea from Chloroform.—M. Spargella finds that the inhalation of oxygen immediately after the termination of anesthesia is of decided advantage in preventing vomiting. He has tested it in a considerable number of cases. Nausea was slight and vomiting absent. He explains the effect of the oxygen thus: the vomiting is produced by excitation of the cortical and spinal nervous centers, the result of an active hyperemia and a bringing to the brain of a larger amount of chloroform than it can bear. The oxygen becomes combined with a portion of the poison, and lessens the excitation of these centers by the chloroform, and thus decreases the reflex vomiting.—*La Riforma Medica.*

EXPERIMENTAL ARTERIAL DISEASE.

Two authors have recently given general summaries of the experimental work in the production of arterial disease, Adler of New York in the *American Journal of the Medical Sciences* for August, 1908, and Heubner in the new *Ergebnisse der inneren Medizin und Kinderheilkunde*. In carrying on such experimental work it was early found that the methods developed in the study of infections were not quite applicable to the study of arterial disease. In infections investigators have to deal with bacteria or their toxins recovered from diseased human beings and allowed to act in the bodies of animals. Arterial disease, on the other hand, is probably the result of some more or less constant and slowly acting causes, yet in the animal experiments gross mechanical injuries or comparatively quickly acting drugs had to be used to produce somewhat similar conditions. For instance, adrenalin injections were often used by the investigators, and when marked aortic degenerations of the aorta were found in rabbits the hasty conclusion was formed that a condition similar to the arteriosclerosis of human beings had been produced by the pressure-raising effects of adrenalin. Soon enough, however, it was discovered that the lesions were usually limited to the aorta, that only rabbits were found to be very susceptible to such injections, and that many rabbits not experimented upon showed similar lesions. These findings, of course, introduced a great element of uncertainty into the results obtained, but, as Adler points out, they opened a new and profitable field of research, namely, the study of spontaneous arterial disease in animals. The net result of the experiments, nevertheless, strengthen the old clinical view that the condition of the arteries depends upon the use they have been put to in the life process of the organism; everything that increases the wear and tear of these important structures leads to their early degeneration and the consequent early senility of the whole body. Among the influences which, in experimental work, take the place of the wear and tear of the struggle for existence Heubner enumerates the effect of adrenalin, injections of ferment into the blood, feeding with putrefying substances, poisoning with the toxins of diphtheria and other infectious diseases, mechanical injury to the endothelial lining of the vessels, artificial nephritis, infection with attenuated organisms, and poisoning with nicotine. The two factors that produce the deleterious effects upon the vessels consist in overstretching of their coats and interference with their nutrition. While the same factors are probably active in the production of human arterial disease their influence is spread over a long period of time and their ultimate sources are much more subtle and mysterious than in the experimental work. For it must not be forgotten that disease or disordered function of any tissue or organ of the body is probably reflected in the composition of the blood, which in turn influences the arteries that act both as passive containers of that fluid and as active users and perhaps modifiers of its elements.

It is thus seen that diseases of arteries offer problems quite other than those presented by the infections, and methods of experimentation used in the latter are little applicable to the study of the former. Still more important is the consciousness of the limitations that are inherent in the experimental study of these affections in the present state of knowledge. Such appreciation of the conditions surrounding research work in this field has not always been shown in the past; not the least important result of the general survey of the work by Adler and Heubner is, therefore, the accent it places upon the necessity of circumspection in drawing conclusions in regard to diseases of arteries in human beings from the results of experimentation upon animals.

MORPHINISM AND THE OPIUM HABIT.

THE opium question is well to the front at the present time. The international conference called together at the instigation of the Government of the United States to discuss action for the abolition of the growth and consumption of opium will meet in Shanghai during the coming January. The opium question in China and in some other parts of the Far East resembles in many respects the drink question in Europe. It is the opium habit that prevail among the Chinese, and it is the drink habit that exists among Europeans. Public opinion and a keen sense of the moral aspect of the affair, together with considerations of health, have brought on a crusade against drink, and the same views characterize the conduct of the coming campaign against the abuse of opium in China. The fight against the drink traffic has been fairly successful, and it is to be hoped that the evils consequent upon the consumption of opium may be checked in China. It may be anticipated, however, that it will be a very long time ere the use of alcohol is abolished in Europe or that of opium in the Far East.

Recently, Sir Dyce Duckworth delivered, in the London School of Clinical Medicine, a clinical lecture on the opium habit and morphinism. Referring to the opium habit among Oriental races he said: "Opium is largely used by natives throughout India and China, and it is certain that in many instances the results are hardly to be regarded as inimical to the bodily tissues. Habitual eaters may take 10 or 20 grains of opium in the course of a day. Some native wrestlers are said to take it while in training. There is found to be variations as to the amount tolerated by different individuals and as to that which produces poisonous effects. That eminent and level-headed physician, the late Sir William Roberts, studied carefully the question of opium eating when in India and concluded that the mischievous effects of it were not so grave as com-

monly believed and that the practice of it under some conditions of native life was probably even beneficial rather than hurtful."

As a matter of fact the Far Eastern peoples have become immune to a considerable extent against the toxic properties of opium in the same way as some European peoples have become immune in some degree against the toxic action of alcohol. Rudyard Kipling, one of the shrewdest observers as well as one of the most powerful of novelists, recognized this fact when living in India. However, the addiction to opium by Europeans is distinctly harmful and very demoralizing. Those who now indulge in the habit, and unfortunately there are a large number of persons who do so indulge, use morphine, generally by means of the hypodermic syringe to satisfy the craving. Sir Dyce Duckworth says that both the alcohol and the drug habits are oftentimes acquired by persons with fine brain and highly sensitive nervous system. He is of the opinion that no violent or sudden measures will ever rapidly abolish the evils of opium intoxication or of alcoholism. Probably the drug habit is more prevalent in this country, just as alcoholism is more prevalent in Great Britain. Both habits are demoralizing and injurious to health, and efforts to check them are deserving of every encouragement.

THE FEEDING OF THE SOLDIER.

The feeding of the soldier differs in many respects from that of the civilian. Meals are more regular, the material, perhaps, is better chosen, and it is fairly well adapted to suit the requirements of men in sound health. That the feeding of the soldier is in general good and the life healthy is demonstrated by the vast improvement that is nearly always effected in a comparatively short time in the physical condition of young soldiers. This is especially noticeable in Great Britain where the majority of the recruits for the army are drawn from a low class of society, many of whom when enlisted are undersized and emaciated, not a few showing signs of degeneracy. Among such as these the beneficial influence of a nourishing diet is most striking. In the course of a year the thin, weedy, pale town youth will often have developed into a sturdy, muscular, and well nourished man.

But although the soldier's diet in the American and British armies is generous and satisfactory, some among the authorities are constantly seeking to change it. Here, it is said, the army cook book is to be revised in the direction of simplicity; in the British army a greater diversity is thought to be desirable. Major Robert J. Blackham read a paper on the subject before the meeting of the British Medical Association held recently in Sheffield. Referring to the results of Chittenden he said that these had received considerable hostile criticism, but it seemed to him that none of the critics had as yet adduced evidence in the form of carefully conducted experiments to disprove the results of his painstaking research. He was of the opinion that here was a line of study in which military physicians might do some epoch-making work. It might be difficult, but he could not think it would be impossible, to induce groups of soldiers in different parts of the empire to adopt a modified dietary under the supervision of officers of the corps, and the results of such investigations might go far to settle some very important questions.

Some feeding experiments have been undertaken in the American army, but not upon a sufficiently wide scale to make the results definitely convincing and really valuable. Investigations of this nature must be conducted among a large number of men and under varying conditions to render them of much scientific or practical worth. It cannot be denied, however, that the British army and in a lesser degree the American army lend themselves favorably to this kind of research. Both are situated in widely diverse climates and the men in most respects are eminently fitted to be the objects of such investigations.

Alluding to the feeding of the British soldiers in barracks Major Blackham noted that reforms had been introduced, excellent in so far as the diet was varied but to be deprecated in that it was too liberal, while if they accepted the results of Chittenden it was excessive. In European armies generally, including the British army, there was a too great sameness of diet. Meat and biscuit or bread constituted the staple of nitrogenous diet of troops in the field in all the armies of Europe. With the single exception of occasional issues in South Africa little or no attempt had been made to supply such cheap and excellent forms of food as cheese or oatmeal. Joly had suggested that sugar might replace a portion of the meat ration in field maneuvers or actual service, and had further advised that the emergency ration should consist entirely of carbohydrate material, as it was generally accepted that that type of food was chiefly concerned in producing muscular energy.

It is entertaining as well as instructive to read the opinions of scientific men as to the value of certain diets. Scarcely has Sir James Crichton-Browne demolished—to his own satisfaction, at least—in eloquent phrases the fads of such men as Fletcher who urges extreme mastication, and others who have advised that much less food in general should be eaten than is ordinarily the case, and little or no meat, than among others Major Blackham propounds an almost opposite view. Sir James Crichton-Browne contended that all who are able should eat generously and take plenty of meat, while the followers of Chittenden hold that very much less, indeed scarcely any, meat should be eaten and that diet in every respect should be more sparing.

The food question is largely one of mode of life and the individual. If a man works at a desk indoors for the greater part of the day he certainly does not need a large amount of food or much meat. But if he is doing manual labor in the open air, he can eat and digest easily a considerable quantity of meat, and experience does not go to show that such a diet harms him. Therefore it would appear reasonable to argue that a soldier on active duty benefits by a goodly proportion of meat in his rations. With Major Blackham's conclusions that a varied diet is the best for a soldier, as indeed it is for anyone, there can, of course, be no grounds for dispute.

LEAD POISONING.

The frequency of lead poisoning in lead workers, plumbers, painters, and glaziers is well known, and in the presence of suggestive symptoms in persons of these trades the correct diagnosis is usually made. But in addition to lead-poisoning as an "occupation disease" mild forms of plumbism occur in other individuals exposed in a greater degree than usual to the effect of lead, or perhaps suffering from an increased susceptibility to the toxic influence of that metal brought on by some unusual circumstances. These are the cases that baffle physicians by the obscure pathological picture they often present, until the history of the patient is carefully inquired into and the rôle of lead in the production of the symptoms is discovered. In a recent number of *International Clinics* (Vol. II, Eighteenth Series) James J. Walsh considers this aspect of lead poisoning in relation to several curious cases of the affection. One of his patients was a bartender who lost all power in his hands and was treated for a long time and ineffectually by the administration of salicylates, the diagnosis of some obscure form of rheumatism having been made. One point in his history was suggestive, and that was the fact that he was accustomed to drink a good deal of what he termed "soft stuff," being a total abstainer, yet compelled to drink something when "treated" by his customers. The bottles containing these beverages were closed with old-fashioned lead stoppers and the carbonic acid gas dissolved in the beverages made them much better solvents of lead than uncharged fluids. Eliminative treatment led to quick recovery of the patient and proved the correctness of the diagnosis.

Another patient, whose history is related by Walsh, was a wealthy man who developed symptoms of plumbism soon after removing to a newly-constructed country house. The only etiological factor in his case consisted in the presence of lead connections in the plumbing of the house; as the others in the household were quite free from symptoms the presence of an increased susceptibility to lead had to be assumed. The replacing of the lead pipes by those of cast iron soon led to the amelioration of the symptoms and finally to complete recovery of the patient. Still another patient was a young woman, a literary worker, who developed symptoms of lead poisoning after painting one room of her apartment. In her case, also, an abnormal susceptibility to the metal was probably present, as the amount of lead that entered her system must have been extremely small. Other similar cases of plumbism in persons occasionally or accidentally brought under the influence of lead are recounted by Walsh as well as by many other authors. Thus M. Allen Starr tells of a servant who developed lead paralysis from drinking water early in the morning without properly washing out the pipes by allowing the first portion of the water to escape, and instances of lead poisoning brought about in the course of the administration of remedies containing lead, such as plasters and ointments, have been reported.

Careful consideration of possible etiological factors ought to give the practitioner a clue to the explanation of obscure pathological pictures resembling lead poisoning. But in addition, clinical pathology has lately discovered a valuable sign of this affection, namely, the basophilic degeneration which may be observed in many red blood cells of the patient's blood. The presence of such stippling of the erythrocytes ought always to be regarded as evidence corroborative of the diagnosis of plumbism, or at least suggesting the possibility of such a diagnosis in the presence of other suspicious symptoms.

Transmission and Autoimplantation of Cancer.

Among students of malignant disease who have carefully followed the course of experimental research in the subject, with its attempts to discover parasitic excitants of this disease, to transmit it to lower animals, to cause its disappearance by the introduction of sera and ferments into the circulation, the conviction has steadily been growing that cancer appears in persons possessing some unknown predisposition to the disease, or at least that the existence of cancer brings about such predisposition to the spread of the disease. Two phenomena treated at length by Roger Williams in his volume on the "Natural History of Cancer," lend support to such a view; one is the every day evidence of the unconquerable spread of the disease in individuals once affected, the other is the less well known peculiarities of cancer in regard to transmission to other human beings and to autoinoculation in the patient. It is a striking fact that not a single authenticated instance of the transmission of the disease to another human being exists. Yet the opportunities for such an accident are certainly present about every cancer patient. Pregnancy is a common event in women suffering from uterine cancer, yet there is not a single instance on record of cancer of the penis that could be traced to transmission by intercourse; the children of cancerous women never acquire the disease, even when such organs as the placenta and the uterus are the seats of the affection; there has never occurred an instance of infection with cancer among the innumerable nurses, students, and doctors who come in close daily contact with cancer patients; finally several experiments have been performed by surgeons who have attempted to inoculate themselves with cancer removed from patients, and none of them has been successful. On the other hand, autoinoculation with cancer seems to be much more common than is usually thought. The skin of the arm kept in close contact with a breast cancer has been infected; the thorax below a pendulous breast affected by cancer has been likewise attacked; the vaginal walls often show foci of disease due to direct contact with uterine cancer, and successful transplantation of cancerous nodules has been performed by surgeons in patients suffering from inoperable cancer. It seems plain that human beings are naturally resistant to any infection with cancer by direct transmission; cancer patients, on the other hand, seem to have lost the power of opposing the invasion of the disease whether by the natural processes of local growth and of metastases or by artificial transplantation of parts of their tumors to other regions of the body. The conclusion seems to be inevitable; the appearance of cancer coincides with, or is followed by some specific changes in the organism, and the nature and cause of such changes may be determined when we have discovered the etiological factors of malignant disease.

Xanthoma.

The structure and pathogenesis of xanthoma, that curious eruption oftenest localized to the eyelids, but not infrequently seen over the whole body, has been the subject of much discussion. The pathological pictures shown by the lesions are quite constant; the nodules are made up for the most part of the so-called "xanthoma cells," consisting of a finely meshed protoplasmic network, and one or more dark-staining nuclei. The meshes, however, are not to be seen in fresh preparations not exposed to the action of alcohol, but sectioned after hardening with formalin; in their stead there appear glistening droplets of some material which has usually been interpreted as fat deposited in the cell or formed by the degeneration of the cell. This view of the contents of xanthoma cells offers no explanation for the appearance of the eruption in such diseases as diabetes and the affections of the liver, accompanied by icterus. Pincus and Pick have, therefore, reviewed the work of previous investigators of this subject, and in the *Deutsche medizinische Wochenschrift* for August 13, 1908, they report findings which are quite at variance with the usual teachings, but which give a more rational explanation of the pathogenesis of the eruption. According to them the substance contained in the meshes of the cells is not fat, but a doubly refracting material, which simulates the staining properties of fat when sudan is used for this purpose, but gives doubtful results with the osmic acid stains. Further microscopical and chemical study of the substance justifies the conclusion that it is some derivative of cholesterin. This finding is in full agreement with the data obtained by Flint, Pages, and B. Fischer, who have shown that great increase in the cholesterin content of the blood takes place in icterus and in diabetes. The chemical and histological character of xanthoma is due, then, not to fatty degeneration or infiltration of the xanthoma cells, but to the deposition within them of cholesterin or its derivatives circulating in the blood stream. This explanation of the pathogenesis of xanthoma leaves unexplained the predisposition of the eyelids to the eruption, and the fact that not every case of severe diabetes with an excess of cholesterin in the blood is accompanied by an eruption of xanthoma. The rare occurrence of xanthoma upon the surfaces of the meninges or in the internal organs is another curious phenomenon that awaits explanation. These problems, however, are of general character, and are concerned with the broad questions of cell physiology and pathology; the special nature of xanthoma, on the other hand, is made much clearer by the observations we have just noted.

Malaria in Young Children.

Malarial infection in young children, especially in infants, is difficult of diagnosis. Yet it is comparatively frequent in malarial districts, according to the statement of M. Gioseffi, in the *Rivista di Clinica Pediatrica*, No. 5, 1908. The intermittence or remittence of temperature is quite irregular, and is so far from being characteristic that it may very easily be mistaken for one of the frequent gastrointestinal temperature rises, or for fever due to other causes incident to infancy. The splenic tumor is not characteristic of malaria, it being found in hereditary syphilis, in various chronic and acute infections, rachitis, anemia, etc. Malarial infection occurs more frequently in children than in adults, owing to the lack of resistance to infections that exist in childhood. In the malarial regions of Italy the population is so poor that the children are fed mainly on vegetables lacking in nourishment, and are nursed very irregularly. In many of the cases if the child is removed from the malarial surroundings and properly nourished a cure will be obtained without specific malarial treatment. A careful examination of suspected children and blood tests are of great importance in malarial regions whenever there is a suspicion of the possibility of infection aroused by irregular fever and other symptoms.

Lumbar Puncture in the Treatment of Epilepsy.

Theoretically lumbar puncture would be indicated in epilepsy if the increased intracranial pressure, existing before a convulsion sets in, were the cause of the latter. In literature we find an occasional report of an epileptic patient treated in this way. Tissot in the *Progrès Medical*, No. 19, 1908, reports ten cases so treated and observed for a long time. His results were all negative. Though large amounts (from forty to seventy cubic centimeters at a time) were frequently withdrawn, the number of epileptic seizures remained the same, as did also the severity of each seizure. Repeatedly convulsions set in soon after the lumbar puncture so that the latter may not even be said to put off an attack. Tissot has proved that the increased intracranial pressure is not the cause of the convulsions, and that lumbar puncture is contraindicated in the treatment of epilepsy.

News of the Week.

Health of the Canal Zone—The report of Colonel Gorgas, chief sanitary officer of the Isthmian Canal Commission, of the month of July, 1908, has recently been issued. As compared with the month of June, the death rate for July, in the Canal Zone, showed a slight increase, but as compared with July, 1907, there was a large improvement. Among the whites the death rate for July, 1907, was 15.72; for July, 1908, 12.69. Among the blacks the rate was 42.58 for July, 1907, and 15.43 for July, 1908, a decrease of more than half. With 38,298 employees in July, 1907, there were 112 deaths; among 44,938 in July, 1908, 55 deaths. The difference in the sick rates for the two years was not so marked, being 28.66 per thousand in July, 1907, and 27.01 in July, 1908; but the gravity of the cases had evidently been greatly decreased. With almost the same sick rate the number of deaths was less than half. During the month no cases of plague, yellow fever, or smallpox appeared in the Zone. The health conditions are, therefore, very satisfactory.

Cholera in the Philippines.—The cholera situation in the Philippines generally has very much improved, but the Navy Department has taken precautions as regards the much talked about visit of the fleet in ordering Admiral Sperry not to permit shore liberty to any of the men, at least not until the fleet returns to Manila in November after its visit to Japan. At the request of the Government the Governor General of the Philippines has made a report to the War Department giving the number of deaths from cholera of white people in the islands since American occupation. The total number, including those among soldiers is as follows: 1902, 162 cases, 85 deaths; 1903, 10 cases, 8 deaths; 1904, 4 cases, 3 deaths; 1905, 12 cases, 7 deaths; 1906, 12 cases, 9 deaths; 1907, 11 cases,

2 deaths; 1908, 14 cases, 5 deaths. The report states that probably no other large port in the East is as free from cholera as is Manila. Fewer cases have also been reported from St. Petersburg, though it is feared that the premature discharge of patients from the hospitals may cause another spread of the infection. In China it is estimated that 30,000 natives have died of cholera in the Yang-tse Valley alone.

No Yellow Fever in Cuba or Panama.—The quarantine against Cuba which has been in effect in all ports of the United States south of Norfolk, has been removed except in regard to the Province of Santiago, the last case reported having been at Havana on September 12. It is thought that yellow fever has been practically eradicated from the island. American methods have also stamped out yellow fever and fever conditions in Panama, and when regulations can be enforced against surrounding countries by Panama, it is expected that there will be no return of it. A sanitary convention has already been signed between Panama and Ecuador, and this will have a good effect on the health of the Canal Zone.

Plague Outbreak.—The plague has made its reappearance in Ecuador with six cases and three deaths. A number of cases of illness and deaths from what is supposed to be bubonic plague have also been reported from Morocco.

Public Health Bureau.—The recommendation of the committee of the American Medical Association and of the Health Committee in favor of the consolidation of all the public health bureaus under one national bureau, was submitted to President Roosevelt on September 27 by Prof. Irving Fisher of Yale University. The President has promised to make the recommendation to Congress in his annual message. The matter was also discussed by Professor Fisher before the International Congress on Tuberculosis.

War on Opium Smoking.—While Japan has not yet notified China that she will withdraw her opposition to the restriction of the importation of opium into that country, she has signified to the other powers that she will do so. Investigation in China has revealed an illegitimate traffic in morphine pills, the use of which has been officially recognized as a cure for the habit of smoking opium.

Defective Children.—Speaking before the Eastern Public Education Association in session in Washington last week, Dr. Darlington, Commissioner of Health of New York, is reported to have said that over 70 per cent of all children examined in the New York schools show evdence of physical abnormalities, most of them remediable under proper treatment.

Death of a Centenarian.—The Rev. Alexander Mans of London, Ontario, died recently at the age of 118 years. He was born a slave, but when fifty years old escaped to Canada, and became a minister of the colored Baptist Church there. He was known as Canada's oldest man.

Ambulance Wrecked.—In a crash between an ambulance of the City Hospital of Newark, N. J., and a trolley car, Dr. George Knauer, the surgeon, and Charles Rust, the ambulance driver, were thrown out and badly bruised and cut. There was no patient in the ambulance at the time.

New Tuberculosis Sanatorium.—Undercliff, a sanatorium for the treatment of tuberculosis at Meriden, Conn., was opened formally by Governor Woodruff on September 22. The sanatorium has been built by the Anti-Tuberculosis Association which was formed last year.

Charitable Bequests.—The Newark Hospital for Women and Children receives a gift of $40,000 in the will of the late James R. Sayre, Jr., of that city.

A number of charities benefit under the will of the late Mrs. Emma A. Tillotson of New York, which was recently filed. Five thousand dollars is given to each of the following institutions: The Home for Incurables, St. Mary's Free Hospital for Children, the New York Society for the Relief of the Ruptured and Crippled, the New York Skin and Cancer Hospital, and the Woman's Hospital. St. Luke's Hospital receives, also, $10,000 for the endowment of two beds to be known as the Luther G. Tillotson and the Emma A. Tillotson beds.

The Flushing Hospital has just received a legacy amounting to $1,000 from the estate of a colored woman, Mrs. Mary A. Shaw, which has been in litigation for three years.

The will of the late Joseph Shineberger of Dillon, Mont., provides that the sum of $25,000 shall be placed in trust until it shall amount to $90,000. Of this $40,000 is then to be used for the erection of a hospital in that city, the remaining $50,000 to be set aside as a permanent endowment fund.

The Presbyterian Hospital of New York receives $10,000 from the estate of the late Henry Suydam Wilson, whose will was recently admitted to probate.

By the will of the late George A. Cotton of Philadelphia the sum of $5,000 is bequeathed to the Samaritan Hospital for the establishment of the Emma C. B. Cotton bed.

The Home for Destitute Crippled Children and a Newspaper Fresh Air Fund of Chicago each received an annuity of $500, and ultimately each institution will receive $60,000 from the estate of David E. Fiske, who died on July 15 of this year.

The Methodist Episcopal Hospital of Brooklyn receives a gift of $5,000, and the Greenwich (Conn.) General Hospital $10,000 under the will of the late Mrs. J. W. Murray of Brooklyn.

Death from Burns.—Following what is said to be an old Slavonian custom, the parents of a small child, in Clifton, N. J., who was recently severely scalded by hot coffee, treated the burns by the application of black ink. Death resulted from blood poisoning.

The National Volunteer Emergency Service held its seventh annual meeting on October 2 in New York. The Director, Major-Gen. James E. Pilcher, who presided, gave a summary of the public services performed by the association since its organization in 1900. Four well-equipped ambulances are supported by the service which are subject to the call of the poor day or night, and are under the direction of the physicians who are teachers in the school for first aid to the injured. Subscriptions to the amount of $15,000 for a hospital to be built in the city have already been received, and further funds have been promised.

Spring Water Analyzed.—The Department of Agriculture extended its work under the Pure Food Act by seizing recently 300 cases and 100 demijohns of a popular spring water for analysis. The Department charges that the water in question contains an excessive number of organisms, among them *Bacillus coli*, and therefore falls under the prohibition against adulterations. It is probable that following this initial analysis other spring waters will be examined.

The Prussian Academy of Sciences has just received a bequest of 30,000,000 marks, or about $7,300,000, from a Berlin banker who died recently.

Emergency Hospital.—A branch of the Boston City Hospital is shortly to be opened in East Boston, in the form of a relief station or emergency hospital. The building is designed to afford treatment more especially for accident cases, such as was recommended for New York in a recent report of the State Charities' Aid Association. The building is three stories high and includes treatment and operating rooms and small wards. Ambulance service is also provided for.

Dr. Luther H. Gulick, for some time Director of Physical Training in the New York public schools, has resigned from that office, the Board of Education accepting the resignation to take effect October 1. Dr. Gulick is also President of the Playground Association of America.

Dr. E. J. Senn has resigned as assistant professor of Surgery in Rush Medical College.

Public Lecture at the Academy of Medicine.—Dr. Charles A. L. Reed of Cincinnati will deliver a public lecture at the New York Academy of Medicine on the evening of Thursday, October 29, upon "The Character, Status, and Economic Value of a National Department of Public Health."

The Chicago University Hospital was opened for inspection on October 1, from 8 to 10 P. M. It is located at Ogden avenue and Lincoln and Congress streets.

The Windham County (Vt.) Medical Society held its annual meeting at Northfield, Mass., on September 23. The following officers were elected: *President*, Dr. P. P. White of Williamsville; *Vice-President*, Dr. Thomas Rice of Brattleboro; *Secretary*, Dr. H. L. Waterman of Brattleboro; *Treasurer*, Dr. F. H. O'Connor of Brattleboro; *Censors*, Dr. A. I. Miller and Dr. C. S. Pratt of Brattleboro; *Delegates to the State Medical Society*, Dr. F. L. Osgood of Townshend, Dr. A. L. Miner of Bellows Falls, and Dr. H. L. Waterman of Brattleboro.

The Kentucky Medical Association held its fifty-third annual meeting at Winchester, Ky., on September 23 to 25. The election of officers resulted as follows: *President*, Dr. I. A. Shirley of Winchester; *Vice-Presidents*, Dr. M. F. Coomb, Dr. B. F. Parris, and Dr. J. C. Carrick; *Treasurer*, Dr. W. B. McClure of Lexington; *Secretary*, A. T. McCormack of Bowling Green. *Orator in Medicine*, Dr. C. G. Stevenson of Clark County; *Orator in Surgery*, Dr. J. S. Pythian of Newport.

The Medical Association of Morgen County, Colorado, was organized recently, and Dr. J. A. Farnsworth was elected President, and Dr. A. F. Williams, Secretary.

The Medical Association of Northern Berkshire (Mass.) held its annual meeting on September 22, and elected the following officers: *President*, Dr. Harry B. Holmes of Adams; *Censors*, Drs. William Galvin and F. H. Howard of Williamstown, and Homer Bushnell, O. J. Brown and J. H. Matte of this city.

The Vermont State Medical Society has postponed its ninety-fifth annual meeting, which was scheduled for October 15 and 16, to October 22 and 23. The meeting will be held in Rutland, and the postponement was made necessary by the inability of the committee on arrangements to secure accommodation for the date first selected because of the meeting of the Vermont State Teachers' Association which is to be held at that time.

Obituary Notes.—Dr. Oscar E. Treutler of St. Louis, Mo., died at his home on September 24, after a lingering illness, the result of a street car accident some years ago, aged 51 years. Dr. Treutler was graduated from the St. Louis College of Pharmacy and from the St. Louis College of Physicians and Surgeons, and was for many years professor of chemistry, toxicology, and materia medica at the Marion Sims College of Medicine.

Dr. Walter T. Clark of Worcester, Mass., died in Portland, Me., while on his vacation, on September 24, from heart disease, aged 46 years. Dr. Clark was graduated from Harvard University in 1886, and from the Harvard Medical School in 1889. He served as city physician from 1894 to 1905, and as medical officer of the Worcester Board of Health from 1905 until his death.

Dr. Alida C. Avery, a pioneer woman physician of San José, Cal., died on September 23, after a long illness, aged 75 years. Dr. Avery was graduated from the New England Female Medical College at Boston, in 1862, and from the Boston University School of Medicine in 1863. Failing health caused her retirement from active practice some years ago.

Dr. Alonzo Good of Muncie, Ind., died on September 24, after a brief illness, aged 65 years. Dr. Good was a veteran of the Civil War, and at the time of his death was vice-president of the Delaware County (Ind.) Medical Society.

Dr. James A. McCready of Monroe, Ohio, died in Christ Hospital, Cincinnati, on September 20, in the seventy-fourth year of his age. Dr. McCready served three years as assistant surgeon in the United States Army, and had been a practising physician in Monroe for over forty-three years.

Dr. Miranda P. Wiswell died at Philadelphia on September 28, after a protracted illness, at the age of 52 years. She was a graduate of Holyoke College and of the medical school of the University of Michigan. She had formerly resided at Milford, Del., and Bethlehem, Pa.

Dr. George W. Holstein died at Bridgeport, Pa., on October 2, at the age of 87 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1843. He had not engaged in active practice for a number of years.

Correspondence.

INFANT FEEDING.

To the Editor of the Medical Record:

Sir:—In your issue of September 26 I find much of interest in relation to infant feeding. But in every instance the laboratory furnishes the information by which the physician is to be guided. Now there are several thousand doctors in this country who do not have access to laboratories, and with the greatest respect for the investigators I must say that these other doctors are doing equally as good work with the little ones as are the laboratory men. Many years ago I wrote a short paper for the Medical Record on infant feeding, giving a plan—not based on scientific experiment, but rather on practical common sense, worked out at the bedside and in the active everyday practice of country work. In using cow's milk the first essential is the care and feeding of the cow; neglect this and no laboratory work will rectify the mistake. The cow should be fed good, clean hay and grain—no corn feed nor pasture, with access to noxious and poisonous weeds and plants; good, pure drinking water, no mud hole mixtures nor questionable poison-laden liquids. Then the plan given by me nearly twenty-five years ago, as follows: Make a hole in the bottom of a pan which is to be corked. Allow the milk to stand in this pan until the cream has risen to the surface, then remove the cork and let one-half of contents run away, reinsert the cork, stir the contents until well intermixed, and add water according to age of child. I always use common salt quite freely, and

in some cases lime water and milk sugar. The reasons for doing all these things will be obvious. I have seen physicians who dip off the upper part of the milk, thus in a way doing the same thing advised in my plan. I want to repeat and emphasize the assertion that unless the cow is rightly cared for, a lot of trouble is apt to result from the use of cow's milk. E. W. Bogardus, M.D.

Reading Center, N. Y.

OUR LONDON LETTER

(From Our Special Correspondent.)

SLEEPING SICKNESS—PHARMACISTS AND COUNTER PRESCRIBING—CONFERENCE OF SANITARY INSPECTORS—SPINAL ANALGESIA—CHOLERA PRECAUTIONS—INSPECTION OF FOOD, NEW LEGISLATION—OBITUARY.

London, September 18, 1908.

The commission for the investigation of sleeping sickness which I mentioned last week is being sent by the Imperial Government under the direction of the Royal Society. Colonel Sir David Bruce is in charge, and this is his second expedition to East Africa in connection with the disease. He will have with him one, if not more, who was with him on his previous mission to Uganda. The members of the commission have been studying for several months various points in reference to the disease. Colonel Sir D. Bruce is of the opinion that nothing very definite has been arrived at as to treatment, though certain broad facts are so far established that they will form a useful basis for the local work. We may take it as certain that the disease is due to a parasite in the blood and that the chief carrier is the *Glossinar palpalis*. Investigation seems to show that it is only infective for about forty-eight hours. The habitat of the fly is restricted to a narrow strip around the shores of Lake Victoria and along large rivers. The Uganda Government has prepared a laboratory and station for the mission two miles from the lake shore in a wild, depopulated part of Chagwe province. This will be the headquarters of the commission, and as the tsetse confines itself to a few yards' depth from the shore, the work can be carried on without its unwelcome attentions. Lady Bruce, who has previously braved the dangers of such missions, will accompany her husband once more. Captain Bateman, R.A.M.C., and Captain Hamerton, R.A.M.C., are also members of the commission, which will start this day week.

The Pharmaceutical Conference opened on Tuesday at Aberdeen, when the president, Mr. Wright of Buxton, delivered an address, part of which is calculated to give pause to medical men. He complained of the present condition of the business of the chemist and attributed it to the competition of cooperative societies and dispensing doctors. He defended counter prescribing by chemists as quite in harmony with the general fitness of things, and held it was as much an offense for doctors to dispense as for chemists to prescribe. This monstrous doctrine should open the eyes of doctors to their folly in sanctioning the establishment of the Pharmaceutical Society without the guarantees they could at the time have enforced. Mr. Wright has done them a good turn in stating openly the view which so many of his fellows entertain. They seem to forget that their own business is merely that of retailers of drugs, sundries, perfumery, soaps and a host of other things. At first, when drugs were annexed, medical men were the only persons dealing in them, except wholesale. By gradual advances the druggists came to annex a considerable amount of business in medical appliances and drugs and went on to dispense. The apothecaries and other doctors were their only competitors and made no fuss about their rivals. The Society of Apothecaries, in fact, neglected to defend their licentiates and went more and more into the wholesale drug trade. At length the chemists agitated for a society of their own to control their business. When doctors mentioned that it would lead to further advances towards practise, the advocates of the movement were greatly shocked and answered: "Oh, no! that can never be; the new society would prosecute such an act and expel the delinquent." The Pharmaceutical Society was established and now what do we see? This claim made without a blush and the audience approving. It should be added that the president expressed the opinion that the society would be justified in striking off the roll a member "who had been proved to be in the habit of prescribing indiscriminately." That is a saving clause of a sort to his assertion of his right to prescribe over his counter, and you may be sure the society will do no such thing.

Mr. Wright then dealt with the subject of "patent medicines" and said the increase of their sale had been enormous and was now not far short of a turnover of three millions sterling per annum. To this I would add that this is the measure of a branch of quackery which is mostly due to the cultivation of the pharmacists, which is exceedingly injurious to medical practice, and, what is far more important, a fraud upon the public. In one sense the chemists are the greatest quacks, as they are the eager purveyors of any and every quack remedy.

The president afterward advised young men studying pharmacy to take up research work.

A number of papers embodying the results of researches in pharmacy were submitted to the conference and discussed.

Last week the conference of Sanitary Inspectors was held at Liverpool. The Lord Mayor, Dr. Caton, received the members and in his speech assured them that the citizens fully appreciated their labors.

Sir J. Crichton-Browne was president and in his address paid a tribute to the work of the Liverpool Tropical School, predicting that its researches and those of the sister school in London, if adequately supported, would lead to the control or abolition of some tropical scourges. If it seemed chimerical to talk of abolishing diseases, they must aim at that abolition—first of one disease, then another, until they had a clean bill of health. Only the other day they had had a practical abolition of Malta fever. It was traced to the milk of infected goats and such milk was put under embargo and the fever disappeared. "Could we but similarly abolish two or three diseases which on the large scale are prostrating and disabling in this country, the Chancellor of the Exchequer need have no further anxiety on the subject of old-age pensions."

The president then dwelt upon the hope of extinguishing tuberculosis and pointed out the necessity of preventing contamination of all food and some reasons for expecting final victory. He hoped the reference to the Royal Commission would be extended. Proceeding to deal with intemperance, he spoke of the importance of housing in this respect, and after some consideration of a general sort illustrated the matter by a particular some might call insignificant—the plastering of walls. Often this plaster would be found soft and porous. Then it was but a sponge to absorb and give off noxious effluvia.

Turning to disease carriers, he said that to catch a house fly and make it walk over a prepared gelatin plate and treat that in an incubator was to obtain an exact tracing of its itinerary in a heterogeneous flora of fungi and bacteria, every footstep of the fly being marked by a colony, and in these colonies pathogenic as well as harmless bacteria abounded. He further referred to human carriers of pneumonia and typhoid and the great length of time the latter might be so.

The Lord Mayor, Dr. Caton, contributed to the congress a paper, illustrated by lime light views, on sanitation in ancient Greece, where the value of open-air treatment was recognized as it is with us to-day.

Spinal analgesia seems to be making steady if slow progress. The early reports of unfavorable cases no doubt arrested for a time its adoption, but greater care has given better results and the tendency to extend its use seems growing. Mr. Barker did much toward making the plan more popular by using a liquid of higher specific gravity than the cerebrospinal fluid in order that it might by its own weight fall to the lowest part of the canal. He has recorded over 200 cases operated on in this way with constant success. Spencer and Houghton have contributed fifty other cases to the journal of the R. A. M. C., McGavin another fifty to the *Lancet*, and now to the same Mill Renton adds a further fifty. These last include twenty abdominal cases. Failure to secure sufficient analgesia only occurred three times, and failure to puncture twice. No bad after-effects in any case. Dr. Renton used Barker's nickel needles, boiled in plain water, as a trace of soda renders stovaine inactive. The injected fluid was stovaine 5 grains, glucose 5 grains, water 100 minims. Seventeen minims was used each time, and as two of these remain in the syringe the dose would be 15. As a rule he draws off from 2 to 2½ drams of cerebrospinal fluid before injecting. In some patients this fluid spurted out freely, in others it only came drop by drop. Where shock is to be feared this method has evidently a great sphere; also in cardiac or other cases, where general anesthesia is to be feared, Dr. Renton thinks in many cases the patient will choose it, while others will prefer general anesthesia. At the same time, he holds

that the utmost care is required to insure success and safety.

Lieutenant-Colonel Russell, R.A.M.C., is selected to attend the meeting of your association of military surgeons at Atlanta, October 6 to 9.

Precautions are being taken at the Port of London and other British ports against the introduction of cholera, which has established itself in so many parts of Russia. Vessels from infected ports are stopped at Gravesend for close medical inspection. At Liverpool a quarantine will be enforced. You will no doubt hear from other sources of the precautions that are being taken on the Continent in view of the steady advance of the epidemic.

Greatly increased powers have been conferred on the Local Government Board by the new Public Health Act. New regulations were issued yesterday as to the "importation, preparation, storage, and distribution of articles of food and drink." Special regard has been taken in the act to close the loopholes through which many dealers in unwholesome food formerly escaped the punishment they deserved. It is hoped to put an end to the trade of unscrupulous dealers in noxious articles of food and diet.

Another nonogenarian passed away last week besides the two I mentioned. This was Dr. Charles Ray, who died on the 10th inst., nearly 95 years of age. He qualified in 1836, practised in London until about twenty years ago, when he retired. He was a Barts' student. He took M.D. Pisa 1838.

On the 10th inst. there also died Dr. E. P. Paton, only forty-one years old, but whose carer had been unusually brilliant and sad. A Barts' student, he took the scholarship and a gold medal with other honors at the M.B. and B.S., London, passed on to the full M.D. and M.S. in 1891-94, taking on the way F.R.C.S. (1892). He held various appointments, among them an examinership at the Apothecaries' Society, demonstratorship at Barts and the Westminster Hospital. To the last he became assistant surgeon, registrar, dean, and lecturer on surgical pathology. In February last Dr. Paton was struck down by an attack of influenza, followed by paraplegia. He was placed in a ward in his hospital and received every help from his colleagues, who unhappily could do but little for one whom they esteemed; and regret was felt for the broken great career to which he seemed destined.

Fleet Surgeon R. Eustace, M.D., R.H., retired, died on the 11th, aged seventy-five. Educated at Trinity College, Dublin, he entered the Naval Medical Service in 1854 and served that year in Baltic in the Russian war, for which he held the medal; also on the admiral's flagship in the Pacific in 1855, as staff surgeon on the Gold Coast in the Ashanti war, 1873-74, for which he was awarded a second medal. In 1876 the Royal University conferred on him the M.D. (*honoris causa*) and retired in 1879.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 24, 1908.

The Home Treatment of Tuberculosis.—A. K. Stone says that almost every incipient case of tuberculosis could be benefited by a stay at a sanatorium. But even these arrested cases must return home, and so the home treatment idea comes into the consideration of every case. The true condition of the patient must be found, and his ability to labor and do things must be accurately estimated. We should not insist that the patient should leave home if he prefers to stay there. A contented mind cannot be neglected as a therapeutic measure. The patient and physician must be on the best terms possible, and the former must come to the latter constantly for advice as to the details of living. If a physician has a group of cases of about the same stage of the disease he may combine them advantageously into a class. The physician must have an intimate knowledge of the home life, and try to regulate its conditions. Details of rest and work must be regulated as far as possible. Special directions are useless except as to the most general outlines. Some arrangement for outdoor sleeping must be contrived. Many houses are now being built with this end in view. If an out-of-doors bed is not possible, we may use some one of the many forms of indoor tents. Rules for bathing and the water temperature must be regulated according to the patient's habits and his present strength. Personal cleanliness must be insisted on. The consumptive who is raising sputa should have nothing to do with the food supplies of the family. Above all, the physician must not content himself with giving general directions, but must be willing to go into bothersome details.

The Necessity of Providing Employment for Tuberculous Patients.—A. Worcester says that a man coming home from a sanatorium and pronounced cured, cannot have his old employment in many instances because of the rule of some corporations that they will not employ a man afflicted with tuberculosis. This custom is spreading. Every public meeting where the dangers of tuberculosis are explained results in pauperizing families by throwing out of employment incipient consumptives who would themselves be far better off if given suitable employment. What shall be done about it? It is our duty as physicians to prevent the spread of disease. And it is also our duty as physicians to relieve those who are afflicted by disease. This, in many instances, involves finding for them suitable employment. There is not only the economic necessity for this; there is also the therapeutic value for us to keep in mind. In some sanatoria patients are given fake employments, such as drawing and painting and basketry, simply for the therapeutic advantage. It would be far wiser to teach patients useful trades by which afterward they might earn their livings. No consideration of the tuberculosis question is at all logical or complete which does not include this matter of providing the employment for those who are thrown on our hands. If we are going to succeed in exterminating the disease something of this sort must be done. Otherwise our efforts will be wrecked on the economic blunder of forcing a large part of our population into unnecessary pauperism.

New York Medical Journal, September 26, 1908.

Some Points in the Applied Anatomy of the Tonsil.—H. A. Barnes calls particular attention to the crypts and their epithelial lining, and to the capsule. The lymphoid tissue should be studied in connection with the lymphoid tissues in general. Nothing especially new is brought out. The structural strength of the cryptic epithelium is, the author thinks, a very important factor in determining the amount of absorption that may take place through the crypt. This strength cannot be great from a mere mechanical point of view, either against bacterial invasion or absorption of toxins. Other forces must be responsible for immunity to infection. The quiescent tonsil of the adult seems to possess an epithelium which in itself is a fairly effective defense against bacterial invasion.

Injection of Alcohol for the Relief of Trigeminal Neuralgia.—Fifteen clinical histories are presented by J. A. Bodine and F. C. Keller. The method referred to consists of the injection of 2 c.c. of more or less diluted alcohol into or near one or all of the three divisions of the trigeminus at their basal foramina exits in the skull. The solution consists of cocaine, 1 grain; chloroform, 10 minims; alcohol, 3 drams, and distilled water to make one-half ounce. In following out this plan we probably do not often succeed in actually inserting the tip of the needle into the nerve sheath, but by following the simple directions laid down by Lévy and Baudouin, the point of the needle rests within a very small factional part of an inch of the nerve trunk at its exit. The alcoholic solution probably comes in contact with the nerve trunk by diffusion. There is at times a characteristic sudden, shooting pain within the area of distribution of the nerve trunk injected, and we have taken this to mean that the nerve itself has been touched by the point of the needle. Again, this characteristic manifestation is absent, and yet the injection has invariably, in every and all of our cases, given more or less relief for a longer or shorter period of time. The authors believe this method to be within the skill of the average man, though they urge preliminary practice on the cadaver. If any dangers attend the deep injection of the second and third branches, they are not known to practice, nor can they be conceived theoretically. The danger of hemorrhage is reduced to a minimum by the blunt cutting point of the needle used. Beyond a more or less extensive subcutaneous ecchymosis, we have, so far, seen no evidence of excessive hemorrhage. The danger of sepsis carried to the depth of needle penetration is an actual one. Preliminary anesthesia of the skin at the point of needle entrance with weak cocaine solution or plain water, then division of the skin by incision with the point of a bistoury, allows easy entrance of the needle point without danger of carrying the infection always resident in the depths of the skin. These injections should always precede, say the authors, resort to surgical measures.

The Leucocyte Count in Abdominal Surgery.—The paper of J. Douglass is based on an analysis of fifty personal cases. Granting the existence of a margin of error, is it sufficient to invalidate the value of the leucocyte count entirely? According to the author, no. Great variations do exist in both the total and differential counts. In regard to the total count, the leucocytes are certainly increased in suppurative and gangrenous conditions as well as those in which there is an effusion of blood into the peritoneal cavity, but it seems impossible to state that any given

number indicates pus or gangrene. And while the higher counts do, in most instances, indicate pus or gangrene, it must be borne in mind that low counts do not rule out either or both. Concerning the comparative value of the two counts, both showed in a large majority of cases an elevation almost equally relative to the pathological condition. In several in which the total count was at fault, the differential count was equally misleading. And as the differential count seems to follow the total count in such a large proportion of cases, it seems questionable whether the statement that the latter is of no value except as an indication of body resistance, is correct. Also the differential count would appear to show somewhat less variation than the total count, and seems to be of greater value than the latter; but here also it is to be repeated that in the writer's experience there is a considerable margin of error. After all, it is the combination of symptoms which must be considered in any abdominal case. The persistence of vomiting, the amount of rigidity or pain, the sudden letting up of pain with persistence of other bad symptons, indicating gangrene with perforation and relief of tension, the abdominal facies, the poisoned look of the patient, the continued or rising pulse and temperature, all these symptons indicate in the clear case the need of operation. But in the case seen early, where the diagnosis is not clear, where one feels the danger of waiting to see whether the unfavorable symptoms continue or new ones develop, the blood count is of great value. If it is confirmatory it may be an important indication for immediate operation; if negative, it is unreliable in so small a percentage of cases that unless there be present some other symptom pointing clearly to operation, one is usually justified in awaiting further developments.

Some Types of Pneumonia Associated with Inflammation of Adenoid Growths.—A series of cases is reported by E. J. Bero. Their general characteristics were as follows: (1) the temperature was high, but (2) it did not correspond to the severity of the illness nor seem to make the progress unfavorable, and (3) toward the end became intermittent, giving the impression of a series of false crises; (4) its characteristics did not seem to alter in either the presence or absence of otitis media; (5) with the exception of the latter disease, complications were not noted in either robust or debilitated patients; (6) early paracentesis in the ear cases did not seem to modify the course of the general disease; (7) the spleen was not enlarged, no plasmodia were found, and quinine did not modify the intermittent temperature; (8) the course was often protracted; (9) the patient was left inclined to relapses of similar character in instances in which the adenoid growths were not removed.

Journal of the American Medical Association, September 26, 1908.

Arterial Degeneration in the Rabbit.—R. M. Pearce has examined 62 rabbits to determine the incident of spontaneous arterial degenerations. He found spontaneous lesions in 3 to 51 supposedly normal rabbits, excluding those which had been subject to a physiologic experimentation, which might possibly have had some share in the production of the lesions. If these were included, the number would be 7, or 11 per cent. of the whole 62. It would appear, he thinks, that while spontaneous arterial degeneration may occur in the rabbit, it is not so constant a condition in all localities as the findings of Miles and Johnstone would seem to indicate. The occurrence of spontaneous lesions, moreover, does not, in his opinion, diminish the importance of the lesions due to adrenalin, but rather increases it, as an example of a lesion, occasionally occurring naturally, but which may be readily produced experimentally. It in no way vitiates the importance of the experimental lesions, but does demand a very careful control study of the rabbits in each locality in which experiments are made.

Cerebellar Tumor.—Three cases of cerebellar tumor are reported by W. Sinkler. Two patients were operated on, one of them twice; the other died suddenly, while waiting for operation. In one of the patients operated on no tumor was found at the time, but growths were found in both cerebellar hemispheres at the autopsy, thirteen days later. In the patient operated on twice the result was a brilliant surgical success, the symptoms were generally relieved, and the patient was apparently in perfect bodily health seven months after the operation, but the vision continued to fail. Sinkler says these two cases show that to save vision early operation is essential. In the case of sudden death the tumor was one that was capable of being rapidly removed, and he thinks that if the operation had not been delayed the patient might have been saved—another indication of the importance of early operating.

The Meatomastoid Operation.—W. L. Ballenger calls attention to the modification of the mastoid operation, as practised by him, to which he gives the name meatomastoid operation, as it consists (a) in the removal of the posterior wall of the bony meatus as deep as the annulus tympanicus, and (b) the complete exenteration of the mastoid cells. The remnants of the membrana tympani and the ossicles are not disturbed. The technic followed is like that recommended by Heath, but more radical in the removal of the pneumatic cells of the temporal bone and in the greater pains taken in making the bony walls of the mastoid wound smooth and applying the Ballance plastic skin flaps to its surface. The cells should be completely removed to insure proper drainage and ventilation, the walls, being rendered smooth, leave no recesses for foci infection, and the proper use and adjustment of the plastic meatal flaps is one of the most important points of technique in the surgery of chronic sclerosing mastoiditis, as the sclerosed bone is inadequately supplied with nutrient blood-vessels to support healthy granulating tissue. The details of this part of the operation are given fully. Ballenger also makes a point in regard to the dressing. If the wound is packed with gauze, the secretions saturate it, causing irritation and infection, and when it is removed the granulations are injured. If, on the contrary, the drainage dressing consists of a small wick of gauze within a rubber tube, its removal causes little disturbance, the granulations are not bathed in secretions as the drain is only in contact with the most dependant part of the wound, and they are carried out to the external absorbent dressing which also protects from external infection. Since using this plan of drainage he has had better results. The rationale of the meatomastoid operation is based on the promotion of healthy granulation tissue and epidermization of the walls of the mastoid wound, and the establishment of ample drainage, which is accomplished by diverting the secretions from the mastoid antrum and cells through the windows in the posterior walls of the meatus, into the external auditory meatus, and by passing blasts of air *viâ* the aditus ad antrum through the middle ear. With the above conditions secured in properly selected cases, the results will be as good as with the radical operation, and in one respect better, namely, the hearing will be much improved, often approaching normal. The meatomastoid operation is contraindicated in: (a) all simple cases curable by nonsurgical and minor surgical treatment through the external meatus; (b) all cases curable by proper surgical attention to the epipharynx and posterior ethmoidal and sphenoidal sinuses; (c) cholesteatoma of the tympanic cavity; (d) epidural abscess with its atrium of infection through the tegmen tympani; (e) brain abscess; (f) infection, suppuration and necrosis of the labyrinth. It is, of course, contraindicated in any case in which it fails for any reason to remove all morbid material and secure adequate drainage. It is indicated in other cases in which simpler measures have failed.

Restoration of the Conjunctival Sac.—M. Wiener describes and illustrates a method which has been successful in his hands in meeting the difficulty experienced in securing a suitable socket for an artificial eye. It applies to cases in which there is still a small amount of conjunctiva left. This is carefully dissected out to form a conjunctival covering for the lower lid, and the bulbar surface is covered with grafts taken from the thigh and applied on a previously shaped lead plate. The illustrations are necessary to supplement the description of the operation, which he claims secures a sufficiently deep lower sulcus, the lack of which has been the chief cause of previous failures. Two cases are reported.

British Medical Journal, September 19, 1908.

Oral Sepsis.—T. Wakefield calls attention to the advantages of tincture of iodine which he uses with an equal portion of tincture of aconite for disinfecting the pockets at the roots of the teeth. The iodine is, of course, a powerful disinfectant, and the fact of its being dissolved in spirit causes it to penetrate into narrow crevices which a watery solution will not do. If a drop of water is placed at the root of a fingernail, it remains where it is placed or falls off. If a drop of tincture of iodine, or of plain spirit, is placed in the same position, it at once diffuses itself all round, and also under the nail. The moisture of the mouth does not prevent this, as may be seen by moistening the fingernail with saliva and then applying a drop of tincture of iodine.

The Treatment of Cholera—R. W. Burkitt details his experience with cholera in Assam. Naturally, the general sanitary conditions with which he has had to contend have been of the worst possible description. He says that since he began treating all cases as early as possible by hypodermics of one-quarter or one-half grain of morphine, he has not lost one patient, provided he was injected early

and before very profound collapse had set in. Many cases have been injected, with the happiest results, even when in the most profound collapse—apparently moribund, in a state when vomiting and diarrhea and almost all signs of life have gone. Children do as well as adults. After cholera, in a certain number of cases, a typhoid condition ensues which needs careful nursing and dieting; in this state he has lost a few patients owing to the want of these necessaries. The hypodermic injection of morphine is the first of two essential factors in treatment, the other is water in enormous quantities every few minutes while awake from start to finish. If the patient is terribly collapsed he gives the morphine first and immediately afterward saline intravenously. It is useless to give water by the mouth then, as it will only excite vomiting and increase the collapse. He has never seen a case where the injection did not in a few minutes stop vomiting, diarrhea, colic, and cramps, and give perfect rest, and in the majority of cases sleep from five to eight hours. In most cases immediately the morphine has taken effect and before sleep supervenes the patient asks or makes signs for water and drinks plentifully, mostly without further vomiting; when the patient wakes the collapse has to a large extent gone, his pulse has returned, his sunken appearance has changed, and he asks for water constantly. He sometimes vomits once or twice eight to twelve hours after the injection; this is due to the morphine, and is quite different to the vomit of cholera.

The Lancet, September 19, 1908.

The Pathogenesis of Tabes Dorsalis.—The paper of T. A. Williams is essentially a review of recent literature on this subject. He calls special attention to the work of Nageotte, who indicated the constancy of lesions on the radicular nerve at the point where it receives its meningeal sheaths. These lesions correspond to one or other stages of the granulomatous process, varying as they do from simple roundcell infiltration to granuloma, and even breaking down with formation of cavities. They are due to primary chronic meningitis, evidenced by the lymphocytosis found by spinal puncture during life and post mortem when skilfully looked for, although the tendency of the process to resolution and fibrous tissue formation leaves only a slight thickening in the membrane, already fibrous by nature. The changes in the cord are consecutive to this. That this is so is proved by similar changes of the posterior column after disease of, or experimental section of, individual roots and by the changes occurring in the mechanical affection of the radicular nerves due to the increased intraspinal pressure caused by the growth of cerebral tumors. The noxa falls upon the root fasciculi very disparately, and this corresponds to the disparate nature of the sensory troubles, which do not preponderate so much as formerly supposed upon the fibers which subserve the sense of attitudes and of muscular movement; for it is now definitely shown that cutaneous sensations are always involved more or less, though probably later in the disease. The superficial lightning pains and the psychometric analysis of the sensibility of tabetics are an index to this. It is certain that impaired sense of attitudes is always accompanied by impairment of the deep pain sense and of perception of the vibrations of the tuning fork by the bones, and as these functions are conveyed in the same peripheral path while they are separated within the cord, clinical evidence is in entire harmony with the pathogenetic theory advanced by Nageotte. The data furnished by the optic nerve symptoms are similarly best explicable by a meningeal affection, involving in this case not a posterior root but a homologue of an intraspinal path. The tabetic symptoms referable to the sympathetics do not differ from those produced by experimental section of the spinal roots nor from those in syringomyelia which, however, alters the cell bodies in the intermedio-lateral column. The anterior roots are not unaffected, but the relative absence of serious myopathies early in the disease is accounted for by the rapid regeneration of the fibers. This is shown by the *terminaisons en croissance* exhibited by Nageotte's preparations and by the results of section experiments. The regeneration of the posterior root fibers extends only to Redlich's ring at which they lose the neurilemma sheath. Finally, evanescent lymphocytosis and reflex iridoplegia, the two most characteristic signs of tabes, are found in many cases of syphilis without other tabetic symptoms; indeed, both sometimes occur in the secondary stage, the former in as many as 40 per cent. The contention of Babinski and Nageotte is therefore accepted that a chronic syphilitic meningitis is responsible for what has been called tabes dorsalis, and that it was formerly disregarded on account of the tendency to the occurrence of resolution and fibrosis of the lesions.

A Case of Severe Vertigo and Tinnitus; Destruction of the Labyrinth; Cure.—The patient of M. Yearsley was a man of 47 years. The method which the author adopted consisted in the simple opening of the cochlea vestibule and canals with the destruction of the ampullary soft parts, and was not accompanied by the severe constitutional disturbance which has followed in some instances in which only one or more canals have been removed. In the author's opinion, the attacking of the labyrinth by the way of the radical mastoid operation is more scientific and certainly more justifiable and less dangerous than the attempt to divide the auditory nerve in the skull. The case described by the author is the ninth operation of the kind. A detailed clinical history is given and must be consulted in the original by those interested.

An Unusual Type of Leukemia Complicated by Synovitis in a Youth, the Subject of Ichthyosis.—The patient of R. Waterhouse was a young man of 20 years, and the chief points of interest in the case may be summarized as follows: (1) the presence of ichthyosis, unusual in that the flexor surfaces were implicated to a greater extent than the extensor. (2) The supervention of a condition of leukemia characterized by deposits of lymphocytic cells in the lymphatic glands, bone marrow, spleen, liver, kidney, and elsewhere, but anomalous in the profundity of the anemia, the absence of increase in the total number of leucocytes in the blood, and in the presence of free iron in the liver and spleen. (3) The occurrence of a symmetrical synovitis of the kneejoints due to a leukemic invasion of the synovial membrane. (4) The fact that the patient had only one kidney. Death came rather unexpectedly after a short period of restlessness and dyspnea. Full autopsy findings are given.

A Case of Traumatic Subdural Hematoma, Trephined Three Months After the Injury.—G. H. Hume narrates the history of a man between 50 and 60 years of age who fell off a bicycle and received a cut on the back of the left side of the head. After a short period of unconsciousness the man picked himself up and went about his affairs as usual, but felt indefinitely ill and had a constant anxiety and depression. Later, symptoms suggestive of brain pressure came on. It was thought that a tumor might be present, and trephining was decided on, it being now three months since the injury. The posterior parietal region was laid bare by a large flap reflected downward. The cicatrix of the wound was included in the upper and posterior angle of the flap and the underlying bone showed no trace of injury. Three trephine discs were then removed and the intervening piece of bone was cut out with a guarded Gigli saw, so as to expose the upper Rolandic area. The exposed dura mater bulged and looked bluish, and when it was incised a quantity of porterlike fluid gushed out to the estimated amount of five or six ounces. When the exposed dura mater was fully laid open a large cavity extending downward and forward and loosely occupied with blood clot came into view. Many portions of the clot were adherent to the under surface of the dura mater (parietal arachnoid); none of the clot adhered to the visceral arachnoid. These adherent portions were scraped away with the sharp spoon and while this was being done it was noticed that the surface of the depressed hemisphere was slowly rising. In no long time it had risen to the normal level. A gauze drain was placed in the subdural space to prevent reaccumulation of fluid, and the operation was finished with the suture of the dura mater and the readjustment of the scalp flap. The bone was not replaced. Recovery of function was immediate though gradual. His mentality became normal as did his power of speech and the use of the arm and leg which had been affected on the right side of the body.

Berliner klinische Wochenschrift, September 14, 1908.

Antitrypsin in the Blood.—Von Borgmann and Meyer have examined 120 patients for the presence of antitryptic properties in the blood. In over 90 per cent. of cancer patients the antitryptic power of the blood serum was markedly increased, but on the other hand over 20 per cent. of noncancerous patients showed the same phenomenon. The reaction, therefore, is not specific for cancer, but may serve as a corroborative evidence in diagnosis; the absence of the reaction should be considered strong evidence against the presence of cancer, being absent in a little over 5 per cent. of the cases only. The test is especially valuable in suspected malignant disease of the internal organs where operation is to be recommended if the diagnosis of cancer is well supported. The absence of the reaction should act as a strong reason for not recommending such an operation. The nature of the reaction has not been satisfactorily explained either in normal or in pathological cases. Its frequent presence in malignant disease may, perhaps, be traced to the proteolytic ferments which have been found in tumors and which are probably absorbed by the blood.

Trauma in Inflammations of Joints.—König says that

trauma is quite frequently the starting point in acute suppurative gonorrheal or chronic tubercular joint disease. The trauma need not be of penetrating nature, nor is it usually very severe in character. The inflammatory phenomena may begin immediately after the occurrence of injury or after some time has elapsed. In case of tuberculosis the infection is caused either by the free bacilli in the blood or by the bacilli included in small caseating masses that reach the blood-vessels from some tuberculous center. The synovial form of tuberculosis is frequently a consequence of trauma to the joint; if the neighboring bones have been injured the primary foci of disease may develop in them. Suppurative affection of the bones may appear many weeks after the causative injury had occurred, time being taken by the formation of the abscess within the bone, and the breaking through into the joint. But pain, discomfort, interference with function and swelling are usually present in more or less marked degree from the time of injury to the appearance of manifest joint symptoms.

Münchener medizinische Wochenschrift, September 15, 1908.

A New Bone Lesion in Childhood.—Kohler has observed three cases of a hitherto undescribed affection in children which was characterized by pains in the dorsum of the foot and slight limping. The feet were also painful on pressure. No points of interest could be obtained from the family or past history of the patients. Röntgenological examination showed marked changes in the navicular bones. They were only one-half of the normal size; the contour was greatly changed; the lime content was much increased as shown by the intensity of the shadows; the compact and the spongy portions were badly differentiated from each other. In one case the patella showed similar appearances. The condition lasted from two to three years and was followed by complete recovery, both as far as the symptoms were concerned as well as the anatomical structure of the affected bones, as far as could be judged by repeated *x*-ray examinations. Tuberculosis, syphilis, osteomyelitis, rachitis, could all be excluded. The special localization of the disease, the symptoms, and the course are quite different from the described affections of bone, and the condition must be considered to be a new disease until further light is thrown upon it.

Trephining in Choked Disks.—Hippel says that choked disk is only a symptom of disease, but as it threatens the patient with rapidly appearing blindness it must be considered by itself. The use of mercury and iodine in this condition is usually fruitless. Recently, palliative operations have been performed, over 220 cases being reported in literature. In one hundred patients the choked disk disappeared after the operation, but vision was improved in only sixty-one cases. The prognosis of the operation is good if it is performed in the early stage of disease, that is, when the vision just begins to be affected. In case syphilis is diagnosed specific treatment must be persisted in, but it has been shown that gummata of the brain are very slowly affected by such treatment; often, therefore, decompression must be performed in order to save the eyesight of the patient while he is treated. In other cases lumbar puncture may effectively remove the intracranial pressure. The operation of decompression is quite dangerous in itself and the patient or relatives must be acquainted with this fact. Often in addition to the improvement in eyesight the severe headache is improved and vomiting becomes rare. The future may bring better procedures for dealing with symptomatic choked disk, but at present the decompressing operation is fully justified.

Deutsche medizinische Wochenschrift, September 17, 1908.

Treatment of Hysteria.—Meyer says that in local hysterical conditions the treatment of the underlying general disease is of greatest importance. The disturbance being of a psychic nature psychotherapy offers most chance of success. At the same time such conditions as anemia, chlorosis, infectious diseases, etc., coexisting with hysteria must be treated in the usual fashion, for they may cause the continuation of the functional disease. The psychic condition in hysteria is very similar to that of the child, for effects are more dominant than the voice of reason, and the treatment of hysteria is properly called the education of the patient. His confidence must first be obtained by careful attention to the usual long story of his ills and the avoidance of all scoffing at his complaints. A complete physical examination should always be performed. Then the treatment followed by the patient in the past should be inquired into so that some ineffective method may not be repeated and the patient thus shaken in his confidence in the doctor. The patient must be impressed with the fact that the affection which to him seems to be of extremely urgent and dangerous nature is only functional in character and that organically his body is quite sound. At the same time care must be taken not to lead the patient to suspect that his complaints are not seriously considered; the word hysteria is best not mentioned before the patient while relatives may be acquainted with the nature of the disease, only if they may be supposed to understand it properly. Medicinal and hygienic treatment must be combined with psychotherapy, both because there are usually indications for such measures, and because the psychical treatment alone may not sufficiently impress the patient. Treatment is best carried out in a sanatorium or at least away from the usual family circle of the patient, where the physician cannot very easily obtain much influence over the mind of the patient. While the use of hypnotism may be justified in experienced hands, this method must be avoided in routine cases and in general practice, for it is quite true that a healthy man may be brought to the verge of hysteria by improper use of hypnotism as often as a hysterical person may be improved by the measure.

Immune Bodies in Tuberculosis.—Spengler says that the immune bodies of tuberculosis are produced and stored by the red blood cells. The bloodserum contains only small quantities such as are needed by the body at any given moment, in answer to the stimulation of the toxins produced by the infecting agents. The transfer of immune bodies from the corpuscles to the serum is accompanied by marked hemolysis. The white cells and the blood platelets also serve as store houses for immune bodies, but they do not act as independent producers of these substances. The principal immune bodies in tuberculosis are lysins and antitoxins and can be prepared as chemically pure substances. They are not proteins. The healthy human being is immune, for his blood contains great quantities of immune bodies that often exceed in amount those found in artificially immunized persons. Disposition to disease results from the diminution of immune bodies which follows disease of the blood or injury to blood-building organs. The immune bodies of tuberculosis may be used in therapeutics in combination with antitoxins against pus organisms, etc.

French and Italian Journals.

The Principal Causes of Death from Diphtheria After the Use of Antitoxin.—Louis Martin has tabulated the causes of mortality in 853 cases of diphtheria treated by serotherapy in the Hôpital Pasteur since 1900. He finds 83 deaths in all, out of which 28, that is about one-third, died within twenty-four hours of entrance, that is before the good effects of the antitoxin had had time to show themselves. This was especially the case in children under two years in whom the diagnosis is generally very difficult. In these children the larynx is often affected and bronchopneumonia is apt to occur. These deaths might be prevented if all cases were injected as soon as any membrane is seen, without waiting for a bacteriological diagnosis. Cases in these young children often come from bad hygienic surroundings which are contaminated, and all young children exposed to diphtheria should undergo preventive injections. Death in the older patients generally results from complications that indicate renal, hepatic, and suprarenal insufficiency. These accidents are generally attributed to nervous lesions caused by the disease, but the author believes them due to a secondary intoxication that develops after the action of the first doses of antitoxin. Such patients should receive a second inoculation as soon as they show renewed symptoms of intoxication.—*Revue Française de Médecine et de Chirurgie*, No. 11, 1908.

Necrotic or Ulceroperforative Angina in Scarlatina.—Felix Langlais describes a form of severe angina in scarlatina that consists of ulceration of the pillars, palate, uvula, etc., ending in perforation, and generally fatal. This form is very contagious and should be carefully isolated from its inception. The ulceration appears at the time of the exanthem as a white patch which does not consist of exudation but leaves a raw surface when a portion is removed with forceps. It extends in depth but not in extent after it has formed. The necrosis may go on to the bone of the palatal vault, and in some cases there is ulceration of the gums and necrosis of the jaw at the site of the incisor teeth, which drop out. The lips and tongue may also participate in the ulcerative process. There is present a very marked infection, with high fever, pain in the throat, inability to swallow or take nourishment, much albumin in the urine, dry skin, and diarrhea. The breath has an infected odor, and a sanious discharge runs from the mouth. The submaxillary glands are much swollen. Death results soon from intoxication and failure to take nourishment.—*Journal de Médecine de Paris*, June 12, 1908.

Book Reviews.

Medical Greek. A Collection of Papers on Medical Onomatology and a Grammatical Guide to Learn Modern Greek. By Achilles Rose. New York: Peri Hellados Publishing Office, 1908.

The several chapters of this little book have for the most part been published in various journals at different times during the past fifteen years, many of them being now out of print and inaccessible. The author has therefore done a service to those interested in the modern form of Greek and in the purification of medical nomenclature in bringing these papers together and placing them within reach of the inquirer. The various articles are not all of equal merit, and some, indeed, might well have been omitted, especially the one entitled "New York Academitis." In that chapter Dr. Rose prints his correspondence with the officers of the academy in reference to his offer to read a paper on "Medical Language" at one of the meetings. The authorities declined the offer for reasons which seemed to them sufficient. The matter had better have been allowed to rest there, for the author only risks prejudicing the cause for which he so strenuously and untiringly labors, by making an issue of the refusal and printing the correspondence. Many of the other chapters are most interesting and valuable, and should be read by all who are concerned in preserving, or rather restoring, the purity of our medical language, now disfigured with so many barbarisms and uncouth terms. The collection includes, in addition to the papers by Dr. Rose, several articles by German lexicographers and writers on the language of medicine, among them a brief epitome of modern Greek.

Die Cystoskopie und Urethroskopie beim Weibe, von Dr. Richard Knorr, Berlin. Berlin und Wein: Urban und Schwarzenberg, 1908.

This book is permeated with that simplicity and directness that stamps the author's personal teachings. His characteristic terseness does not militate against thoroughness and elegance. Like his personal lessons, the book gives far more than the title promises. The object is accomplished in the main by a desire to teach, and secondly by the elimination of historical digressions, questions of priority, of obsolete instruments and of impractical devices and methods. Knorr, with charming modesty, effaces himself throughout, and leaves the conviction that his purpose is to aid, as far as a book can, in the acquisition of cystoscopy and urethroscopy. In this sense the work is invaluable. It also presents very great advantages to those experienced in the arts he teaches. Knorr's conciseness renders a critical review practically impossible. An appreciation of the value of his work can be obtained only by reading it. Its adaptation to the uses of the general practitioner, the gynecologist, the surgeon, makes it far more than a mere reference book. An idea of the practical value of the work may be had by excerpting at haphazard from any of its pages: "Pain during cystoscopy is avoided by firmly maintaining the instrument immobile; by relieving excessive pressure of the bladder contents; by shutting off the current when the lamp grows warm; by renewing the medium when prolonged examination allows it to attain an uncomfortable temperature." He emphasizes that the changes in the bladder due to pregnancy are perceptible as early as the third or fourth week. He illustrates the technique required in the second or third month of pregnancy if cystoscopy should then become necessary. The book (290 pages) is well illustrated. The only exception that can be taken to it, is in the pages explanatory of the lithographic plates; they are primarily too brief, and should front the pictures for easier reference.

The Heart and Sudden Death. By Theodore Fisher, M.D., F.R.C.P. London: The Scientific Press, 1908.

The data from which this little book was compiled were furnished by 2,500 autopsies performed in various London hospitals. There is nothing in it which is especially new, but the author ventures the hope that his observations may be of interest not only to the practitioner but to medical students also, by bringing to mind certain facts not always clearly dealt with in textbooks of medicine.

The Correction of Featural Imperfections. By Charles C. Miller, M.D. Second Edition, Enlarged. Chicago: Privately published, 1908.

Dr. Miller seems essentially modest in his claims as to what cosmetic surgery can do, and he evidences the desire that the subject may be taken out of the hands of quacks and become a well-recognized specialty in the regular school. However, his book is all too brief for this worthy purpose, and needs to be enlarged and dignified by further details than the author has given of his work. For instance, in the correction of "hump" nose "the line of incision lies along the free margin of the nasal bone." This will be of little help to any surgeon who wishes to attempt the operation. The proof-reading is little short of atrocious, and mars what is otherwise an earnest endeavor.

The Principles and Practice of Hydrotherapy. A Guide to the Application of Water in Disease. For Students and Practitioners of Medicine. By Simon Baruch, M.D., Professor of Hydrotherapy in Columbia University (College of Physicians and Surgeons), New York; Medical Director of the Hydriatic Department of the Riverside Association; Consulting Physician to the J. Hood Wright Memorial (Formerly Manhattan General) Hospital; to the Montefiore Hospital for Chronic Invalids; Member of the New York Academy of Medicine; Formerly Gynecologist to the Northwestern Dispensary; Physician for Eye, Ear and Throat to the Northwestern Dispensary of New York City; Physician and Surgeon to the New York Juvenile Asylum, and Chief of the Medical Staff of the Montefiore Home for Chronic Invalids. Third Edition. Revised and Enlarged. With Numerous Illustrations. New York: William Wood & Co., 1908.

Being written by a general practitioner of large experience, this work furnishes the same information on the action of water in disease and in health as do therapeutic works on drugs. Herein it differs totally from other works on hydrotherapy and therefore it has become indispensable to every practitioner who would utilize the most potent remedial measures at his command. The author's method of presenting the subject is especially adapted for the doctor at the bedside. He insists with what would seem persistent reiteration enforced by clinical data upon the real value of water as an important therapeutic auxiliary in the majority of acute and chronic diseases. After making due allowance for the author's seeming overzeal in his propaganda for this neglected remedial agent, the statement of a reviewer of the German translation does not appear overdrawn to the unprejudiced reader. Professor Brieger wrote in the *Berliner Klinische Wochenschrift:* "Here he stands as the true friend at the bedside of the sick and suffering—a friend from whom one may draw counsel on all difficult questions of practice, with the assurance that only that which has been proven, sedulously examined, and critically sifted will be received for the benefit of the sick." The author draws attention to the necessity of careful scanning of the brief histories offered to illustrate the changes of technique demanded by changing phases of disease, and he dwells upon the difference here existing between water and the simpler drug treatment. He appears to know how to put himself in the place of the practitioner in search of therapeutic help in mild as well as desperate cases in which the addition of water may add to the comfort and safety of the patient. His chapter on insanity is a compilation of clinical reports from asylum directors furnished as evidence of the practical results of the author's teaching. Prof. Baruch's continued insistence upon the Brand bath in typhoid fever would seem to be warranted by the recent testimony of eminent clinical teachers, although it can hardly be questioned that this method has lost much of the repute it formerly enjoyed. The author does not indulge in that laudatory advice which too often characterizes works on this subject and with which his earlier writings were sometimes tinged. An additional discussion of observation in private and hospital practice appears to have placed the writer in a calm and judicial attitude which is in evidence in every part of the book. The numerous citations from recognized clinical authorities who are not hydrotherapeutists, testify to the author's desire to hold aloof from misleading praise of his favorite remedy. The book is really a cyclopedia of the uses of water in practical medicine, the possession of which is absolutely indispensable to every physician in active practice. In the historical epitome the American reviewer is proud to discover evidence that his country is not only abreast, but in the advance line of practical hydrotherapy. To this fact is undoubtedly due the compliment of an English, German and prospective French and Italian publication.

Uric Acid as a Factor in the Causation of Disease. By Alexander Haig, M.A., M.D. (Oxon.), F.R.C.P. Seventh edition, with 75 illustrations. Philadelphia: P. Blakiston's Son & Co., 1908.

In this edition of Haig's well known treatise much new evidence is adduced from clinical and experimental sources regarding uric acid in the blood and its relation to capillary circulation, blood pressure, and blood quality. There are some new contributions to the pathology and treatment of diabetes and chorea, and attention is given to recent studies in the amount of food (albumin) required. Diet notes used by Haig in his treatment of the uric acid diathesis are added as an appendix.

Society Reports.

SIXTH INTERNATIONAL CONGRESS ON TUBERCULOSIS.

Held in Washington, D. C., September 21 to October 12, 1908.

(Special Report to the MEDICAL RECORD.)

(Continued from page 604.)

CLOSING GENERAL SESSION.

Saturday, October 3.

HON. GEORGE B. CORTELYOU, SECRETARY OF THE TREASURY, PRESIDING OFFICER, IN THE CHAIR.

President's Address.—President THEODORE ROOSEVELT gave the parting word to the delegates of the Sixth Triennial International Congress on Tuberculosis in the National Museum. His unexpected presence called forth an ovation that lasted for several minutes, the foreign delegates joining in with great heartiness, all of them rising to their feet in compliment to the American executive. The President said that he could not deny himself the privilege of saying a word of greeting. It was difficult for one to realize the extraordinary changes in certain lines of social endeavor during the last two or three generations, and in no other manifestation of human activity had the changes been so far-reaching as in the ability to grapple with disease. It was not so very long, measuring time by history, since the attitude of man toward a disease, such as that of consumption, was one of helpless acquiescence in what he considered to be the mandates of a supernatural power. It was but a short time since even the most gifted members of the medical profession knew as little as the layman of the real cause of diseases like tuberculosis, and of the remedies to be invoked to overcome them. It was an affair of decades when they went back to cover the period in which progress had been made. He then called attention to the work that the United States government was now doing in Panama. "The Isthmus of Panama, which was a by-word for fatal diseases, has become well-nigh a sanatorium; it has become so because of the investigations of certain medical men, which enabled them to find out the real cause of certain diseases, especially yellow fever and malarial fever, and to take measures to overcome them." He said that these unexpected results had followed patient, laborious, dangerous, and extraordinarily skillful work that had enabled the cause of disease to be found and the diseases themselves to be combated with extraordinary success. That success had had its martyrs, for doctors had laid down their lives to secure the results of which he had spoken, showing exactly the same heroism as ever was shown by the soldier on the field of battle. Mr. Roosevelt spoke of the sleeping sickness, a disease which in one region killed 200,000 out of 300,000 inhabitants, a rate of slaughter infinitely surpassing that of any modern war. The chance to control that disease lay in the work of just such men as, of indeed some of the men who, were assembled there. They had come there, however, to combat not a scourge confined to the tropics, but what was on the whole, the most terrible scourge of the people throughout the world. But a few years ago hardly an intelligent effort was made or could be made to war against this peculiarly deadly enemy of the human race. The chance successfully to conduct that war arose when the greatest experts in the medical world turned their trained intelligence to the task. It remained for them to find out just what could be done. The task then would be for the representative of the government to give all possible effect to this conclusion of the scientific men. Now, more and more, the wisest men of affairs realized that the great chance for advancement of the human race in material things lay in the close interrelationship of the man of practical affairs and the man of science, so that the former could give all possible effect to the discoveries of the most unforeseen and unexpected character now made by the man of science. He felt that no gathering could take place fraught with greater hope for the welfare of the people at large than this. He thanked his hearers for what they had done and were doing. In behalf of the nation he greeted them and he hoped they would understand how much their coming here had been appreciated.

Intertransmissibility of Human and Bovine Tuberculosis.—This was a subject of much dispute and many delegates vigorously opposed Koch's statement in disbelief of the unity of the human and bovine tubercle bacillus and his declaration that, up to date, in no case of pulmonary tuberculosis had it been demonstrated that the infection was due to bovine tubercle bacilli. Before the passing of the resolution on this subject, Dr. Koch said: "Gentlemen, you may pass your resolutions, but posterity will decide."

Resolutions.—The following resolutions were passed by the Congress:

Resolved, That the attention of States and central Governments be called to the importance of proper laws for the obligatory notification by medical attendants to the proper health authorities of all cases of tuberculosis coming to their notice, and for the registration of such cases in order to enable the health authorities to put in operation adequate measures for the prevention of the disease.

That the utmost efforts should be continued in the struggle against tuberculosis to prevent the conveyance from man to man of tuberculosis infection as the most important source of the disease.

That preventive measures he continued against bovine tuberculosis and that the possibility of the propagation of this to man be recognized.

That we urge upon the public and upon all Governments the establishment of hospitals for the treatment of advanced cases of tuberculosis; the establishment of sanatoria for curable cases and the establishment of dispensaries and day and night camps for ambulant cases of tuberculosis which cannot enter hospitals and sanatoria.

That this congress indorses such well considered legislation for the regulation of factories and workshops, the abolition of premature and injurious labor of women and children, and the securing of sanitary dwellings as will increase the resisting power of the community to tuberculosis and other diseases.

That instruction in personal and school hygiene should be given in all schools for the professional training of teachers.

That whenever possible such instruction in elementary hygiene should be entrusted to properly qualified medical instructors.

That colleges and universities should be urged to establish courses in hygiene and sanitation, and also to include these subjects among their entrance requirements, in order to stimulate useful elementary instruction in the lower schools.

That this congress indorses and recommends the establishment of playgrounds as an important means of preventing tuberculosis through their influence upon health and resistance to disease.

The HON. B. F. MACFARLAND, Health Commissioner of the District of Columbia, praised the work of the Congress and pointed to the results as of lasting benefit. He said that out of their deliberations and their wholesome differences of opinion would come instruction for all in the great purpose of preventing disease, preserving the health of the nation, and making the future efficiency of the nations secure.

Closing Features of the Congress.—The foreign delegates delivered their messages of farewell. The felicitations were delivered as follows: Dr. Fermin Rodriguez, Argentina; Dr. Hermann von Schrotter, Austria; Professor Denys, Belgium; Dr. Frederick Montizambert, Canada; Dr. Jee, China; Dr. Juan J. Ulloa, Costa Rica; Dr. Diego Tamayo, Cuba; Dr. Bernard Bang, Denmark; Dr. J. B. Piot Bey, Egypt; Dr. Thomas J. Stafford, Eng-

land; Professor Louis Landouzy, France; Dr. Von Leube, Germany; Mr. R. Bengoechea, Guatemala; Dr. G. Soto, Japan; Dr. Detre, Hungary; Dr. Antonio Stella, Italy; Dr. E. Liceaga, Mexico; Dr. N. Th. Tendelo, Holland; Dr. F. C. Harbitz, Norway; Dr. Martin J. Echeverria, Panama; Dr. S. Trimescu, Roumania; Dr. A. A. Vladimiroff, Russia; Paul G. Wooley, Siam; Dr. Camilo Calleja, Spain; Hon. Conrad Cedercrantz, Sweden; Dr. O. Amrein, Switzerland; Dr. Luis Melean Lafinur, Uruguay.

Place of Meeting of Next Congress.—The next meeting will be held in Rome, Italy, in 1911, on the occasion of the fiftieth anniversary of the occupation of the city by the Italian Government. This was at the invitation of Dr. Antonio Stella, who supplemented his invitation with a greeting from King Emmanuel, communicated through Baron Mayor des Planches, Italian Ambassador to the United States.

SECTION ON PATHOLOGY AND BACTERIOLOGY.

Third Day—Wednesday, September 30.

Relations of Air to the Contagion of Tuberculosis; Sterilization of the Air.—Dr. Samuel Bernheim of Paris concluded from the whole of his work that there exists a close relation between the microbes of the air and tuberculosis. The more the atmosphere is full of bacteria the greater the number of tuberculous people. The name of "disease of darkness" had been given to tuberculosis because microbes in general, and particularly the bacilli of Koch, may be kept for a very long period under shelter of light. Under the influence of the normal habits microbes are cast in the air, men breathe them, the lungs keep them, thus producing infection and contagion. The absence or scarcity of cases of tuberculosis in certain climates (higher altitude or the sea) were proofs of the close relationship between the microbes of the air and tuberculosis. The disease is an exceptional one in those climates where the least proportion of bacteria exists. At a certain altitude no seed may be found in the air. For similar reasons a great number of tuberculous people have been observed in the great centers where the air is saturated with bacteria, in overcrowded districts, in places where meetings are held, in hospitals, in prisons, in schools, in barracks, in great shops, mills, and workrooms. Although not denying the possibility of infection by the alimentary tract, Dr. Bernheim maintained that the frequency of such infections could not be compared to that by respiration. He said the best method to get rid of tuberculosis of aerial origin was to look after the salubrity of towns, the hygiene of houses and solar light must be allowed to penetrate in great abundance. Certain artificial measures could be used to lessen the danger; by means of certain apparatus, such as the tub of Dr. Goupil, or Mr. Silbermann's double current chimney, all microbes of the apartments could be destroyed at once and the air rendered rapidly salubrious. He especially advocated the use of these chimneys in apartments, medical and surgical rooms, amphitheatres, and crowded halls.

Sources of Tuberculous Infection.—Dr. W. H. Park of New York said that in the transmission of the disease from man to man sputum is by far the most important factor, while feces was also worthy of consideration. Milk was practically the only means by which bovine tuberculosis is conveyed to man. The relative importance of the two types of bacilli and the exact conditions under which they were transmitted was still a matter for investigation. Expectoration does not convey the infection to the air until it becomes dry and powdered, but droplets sprayed into the air by sneezing and coughing do infect the air immediately. He believed that patients becoming infected from living in houses previously inhabited by tuberculous patients are few, compared with those contracting the disease by living immediately with the tuberculous patients; that the greatest single source of contagion is the living tuberculous subject in the house. Great difficulty, he said, had been experienced in tracing tuberculosis to infected cattle. As to the bovine and human type of bacillus, the former predominated in tuberculous diseases of the joints and glands, which caused only about 5 per cent. of the deaths, while the latter predominated in diseases of the lungs and meninges, causing about 95 per cent. of the deaths.

Dr. McWharter of Riverton, Ala., said that the milk might be infected by the bacilli floating in the air, but it was not logical to say that such an infection was of animal origin any more than it would be to say that the infection of water in such a way was of mineral origin. He thought that feces was a great factor in the transmission of the disease.

Transcutaneous Inoculation of Tuberculosis.—Drs. J. Courmont and A. Lesieur of Lyons presented this paper, in which, from a large number of experiments, the following conclusions were drawn. In the case of the guinea pig, calf, and rabbit, the skin, although apparently intact, readily allowed the tubercle bacillus to pass through under certain conditions, the principal of which are—The bacillus must be sufficiently virulent; it must not be enclosed in sputum, in fecal matter or in tuberculous lesions; but even under these conditions the experiment might be successful, especially with sputum containing bacilli. If inoculation was positive the skin reacts in one of three ways: It showed no trace whatever of the passage of the bacilli; it presented merely a little induration or scab; or warty tubercles, very small and discrete, were observed. In the case of the guinea pig and the calf the neighboring glands became tuberculous even in the absence of any cutaneous lesion. In the rabbit the lymphatic system escaped. General tuberculosis developed most frequently in the rabbit and in the guinea pig if the bacilli were sufficiently virulent; but in any event, it was much slower than after subcutaneous inoculations. In the rabbit the local as well as the general lesions showed marked tendency to cicatrization. In the guinea pig, when inoculated on the inner aspect of the thigh, the inguinal glands were more severely involved than the crural glands; they become enormous and very frequently suppurated. The glandular lesions from subcutaneous tuberculosis did not coincide accurately with the lesions observed in the transcutaneous form. It was observed that the skin itself, although apparently intact, was far from offering an impassable barrier to the tubercle bacillus. Hence, this portal of entry must not be neglected. Many tuberculous infections might result from a transcutaneous inoculation. Absence of a cutaneous lesion was no argument against this mode of invasion as the bacilli might pass through the skin without leaving any trace.

Contribution to the Question of Percutaneous Infection.—Dr. Isadora Spitzstein of Budapest contributed this paper, presenting the results of a series of experiments in the laboratory of the Königen Louise Sanatorium. The report was made upon the experiments conducted with nine rabbits. The skin of the abdomen of these rabbits was first carefully shaven; 48 to 72 hours afterwards portions of a well-tested, virulent pure culture of the human tubercle bacillus were rubbed into this area; the procedure was carried out with such gentleness that even the slightest traumatic injury of the skin was avoided. One of the animals died after 2½ months, but without development of tuberculosis: the other 8 animals lived; 4 were killed after 3 months and 4 after four months. Neither local nor regional changes could be demonstrated in any of them, nor could tuberculosis be demonstrated in any of the internal organs. Neither did the kidneys or lungs, which in rabbits are predisposed to the disease, show any changes. The conclusions were drawn that if percutaneous infection is at all possible it is certainly the most unfavorable mode of infection for the tubercle bacillus; in the case of the rabbit particularly so, as it is decidedly refractory to the disease.

Flies as Agents of the Dissemination of Koch's Bacillus.—Dr. Ch. Andre of Lyons reported the results of his investigations on this subject. He said flies were active agents in the dissemination of Koch's bacillus, because they were constantly going back and forth between contagious sputa and feces, and food stuffs, especially meat, fruit, milk, etc., which they polluted by contact with their feet and with their excretions. The experimental researches of the author showed that flies caught in the open air did not contain any acid-fast bacilli that could be mistaken for the bacillus of Koch; that flies that had been fed on sputum evacuated considerable quantities of bacilli in their excretions; the bacilli appeared six hours after ingestion of the sputum and some might be found as long as five days later. These flies therefore had plenty of time to carry the bacilli a great distance. Food polluted by flies that had fed on sputa produced tuberculosis in the guinea pig. Flies readily absorbed bacilli contained in dry dust. Flies caught at random in a hospital ward produced tuberculosis in a guinea pig. The practical conclusions were that the sputa and feces of tuberculous subjects should be disinfected; flies should be destroyed as completely as possible; foodstuffs should be protected by means of covers made of wire gauze.

The Possibilities of Infection from Table Utensils at Sanatoria.—Dr. J. Woods Price of Saranac Lake, New York, presented this paper. Forks, spoons, teacups, and milk glasses in constant use by advanced tuberculous patients were examined. First, 30 forks and 25 each of spoons, tumblers, and teacups were chosen immediately after ordinary good washing, but not sterilization; they were cleansed with sterile 5 per cent. sodium bicarbonate solution by means of sterile cotton swabs, and the washings distributed among 56 guinea pigs by subcutaneous injection. All pigs were killed in 41 days and found to be free of tuberculous infection. Several months later 5 articles of each sort, immediately after use and before washing of any kind, were cleansed as described above and the washings injected subcutaneously into guinea pigs. These animals also were killed in 41 days after inoculation and all were found to be tuberculous, except those inoculated with the washings from the milk glasses. Later, the first experiment was repeated with the use of 6 articles of each kind, and the washings were distributed among 12 guinea pigs, with the same result. Smears made on slides from the glands and spleens of pigs used in the first and third experiments and examined microscopically for tubercule bacilli were found to be negative in every instance. He concluded that, while the sterilization of tableware used by consumptives was not to be discouraged, the danger of infection from that source did not seem to be great.

Opportunities for Infection.— Dr. S. Matejin of Budapest performed a series of animal experiments in the laboratory of the Koeningen Elizabeth Sanatorium, to determine to what degree tuberculosis infection could be conveyed through the various factors in the everyday life of a tuberculosis sanatorium. Thirteen guinea pigs and eight rabbits were employed for the experiment. Some of them received subcutaneous inoculation of a suspension in sterile water of ordinary house flies; the flies were first washed off, then dried and rubbed into a fine powder, then suspended in sterile water, which was finally centrifugated. Others were inoculated with the maceration fluid of parts of letters which had been moistened by the saliva of individuals who sought admission to the sanatorium. Still others were treated with wash water from the door knobs of institutions; door knobs used considerably by patients of the institution were washed with cotton pads, moistened with sterile water, the water being then squeezed from them. The last few animals were treated with the wash water from pieces of money handled by patients in the institution. Of the 21 animals only one developed tuberculosis; this was a guinea pig treated with the maceration fluid from one of the letters of an individual seeking admission. It would seem, therefore, that the sum total of light and air, as well as the many provisions to prevent the conveyance of the germ of infection in the conduction of a sanatorium (the careful collection of the sputum, the careful cleansing, the covered state of the cuspidors), in reality attained their purpose.

In the afternoon of this day there was a joint session of the section on bacteriology and pathology and that on tuberculosis in animals.

The Relations of Human and Bovine Tuberculosis.—Dr. Robert Koch of Germany confined himself to the practical side of this question. The results of his experiments, which he had undertaken in connection with Schutz and which he had communicated to the British Congress in 1901, were: 1. The bacilli of bovine tuberculosis were different from those of human tuberculosis. 2. Human beings might be infected by bovine tubercle bacilli, but serious disease from this cause occurred very rarely. 3. Preventive measures against tuberculosis should therefore be directed primarily against the propagation of the human tubercle bacilli. He had not expected his views to be accepted as final, but had asked scientists to repeat the experiments. This had been done. The animals used for experimentation had to be entirely free from spontaneous tuberculosis. Since the earliest stages of tuberculous infection could not be recognized with certainty, this source of error could be eliminated only by experimentation on long series of animals, for experiments on too small a number of animals carried no weight. Single exceptions in long series of experiments usually depended upon experimental error and should be valued accordingly or the whole series repeated. The inoculation of animals should be made subcutaneously with weighed quantities of a culture of tubercle bacilli. The best results had been obtained with doses of ten milligrams. He had never held that the human and bovine tubercle bacilli were two distinct species, but only stated that they differed from one another in certain characteristics, which were of the greatest importance in combating tuberculosis. Some had attempted to refute him by showing that the bacilli of the human type might be transformed into the bacillus of the bovine type and *vice versa* by passage through animals or by cultivation in artificial media. In this connection he repeated that he was interested only in the practical significance of the difference between the two types of bacilli. All competent investigators agreed that the tubercle bacilli of human origin and those of cattle differed. Dr. Koch pointed out these differences and said that to his knowledge the bacilli of the human type had never been demonstrated in cattle, but the bacilli of the bovine type could occur in man. They had been found in the cervical lymph glands and in the alimentary tract. With few exceptions, however, these bacilli were but slightly virulent for man and remained localized. He thought the few cases in which bovine tubercle bacilli had been said to have produced tuberculosis in man were not above suspicion. Of all human beings who died of tuberculosis eleven-twelfths died of pulmonary tuberculosis. One would have expected investigators to have searched for the bovine tubercle bacilli in these pulmonary cases instead of in the cases dying of other forms of tuberculosis. Up to date in no case of pulmonary tuberculosis had the tubercle bacillus of the bovine type been demonstrated. If further investigation should establish that pulmonary tuberculosis was produced by the tubercle bacillus of the human type exclusively, then the question would have been decided in favor of the view which he had upheld, and we must direct our regulations for combating tuberculosis primarily against the tubercle bacilli of the human type.

Relation of Human and Animal Tuberculosis.—Professor Theobald Smith of Boston said that the difference between the bovine and human type of tubercle bacillus could

readily be determined by any skilled bacteriologist, and that it had been found that, roughly speaking, perhaps half of certain kinds of tuberculosis in children, such as those of the glands of the neck and the abdomen, were due to infection from milk. Prof. Smith discussed the doctrine which assumed the possibility of a transformation of the bovine into the human type of the bacillus, and reviewed the various experiments which had been made in Europe and in this country. He agreed with some of the investigators that these bacilli could be modified to a certain extent, but that this modification did not mean a change of type, and that any transformation from one type into the other had still to be demonstrated. He gave illustrations to show that tuberculosis in man might be very prevalent where tuberculosis in cattle did not exist. He held that any regular or wholesale conversion of bovine into human bacilli in the human body was contraindicated by most of the evidence presented.

Dr. G. Simms Woodhead of Cambridge, England, said that in discussing this question he was somewhat hampered by the rules of the English Tuberculosis Commission, which forbade him giving the results of experiments unofficially. On one farm they confined the herd on which experiments with bovine tuberculous were being made; on a second farm at a distance those cattle that were being experimented on with the human bacilli were confined; and on a third the laboratory work was carried on. They had taken the greatest care to have the animals which were being experimented on with bovine tuberculosis free from that disease in the start, and to this end cattle had been brought from the Isle of Jersey where tuberculosis among the cattle was unknown. The same was true with regard to the animals experimented on with the human form of the disease. Thus the objections raised by Dr. Koch had been attended to. They found that the bacilli from a large number of cases of alimentary tuberculosis were virulent enough to produce tuberculosis in cattle, or the bacilli had become so modified after they were ingested into the cattle. In feeding the sputum they took it from sources where everything given the patients, food, dishes, etc., were sterilized. In the German Imperial Commission and in the Royal Commission in England they had found that 20 per cent. of the cases of tuberculosis occurred in children under five years of age, and one-third of these were apparently due to the bovine type of bacillus, isolated from human beings. He believed that the bacillus underwent slow modification in virulence or in morphological characteristics. Many of his opponents followed along the line of Prof. Arloing, who said that it was difficult to establish any distinct difference between the two kinds of germs, but in general the bovine was more virulent. In developing in the human system a variation of type was produced. There seemed to be no ground upon which to base the variation of type. It might be that man presented a lesser receptivity to the bovine type of the disease. A great difference could be detected between human bacilli from different sources. He thought the percentages arrived at by the British Commission open to criticism, and further study and experiment were needed to prove whether bovine tuberculosis could infect human beings.

Variations of Tubercle Bacillus.—Professor F. Arloing of Lyons, France, expressed himself as a stanch adherent of the doctrine of the unity of the tubercle bacillus. In former experiments he had shown that there were great differences in virulence in the lesions of all forms of tuberculosis. The range of virulence extended from a virulence comparable to that of the most active bovine bacilli to an almost complete disappearance of the power to produce tuberculosis. He presented the varieties of bovine and human bacilli which succeeded in producing by special methods of culture which lowered or increased the virulence, or modified the character of the virulence to the point of making it like that of the avian bacillus. He showed that the virulence of the avian bacillus could be modified like that of the bacillus of mammals, either by spontaneous or experimental influences. From the medical standpoint, the variations explain the differences observed in the gravity and course of tuberculosis; they showed the desirability of possessing prognostic aids as well as experimental methods of diagnosis, and they threw an interesting light on the significance of the clinical means which were employed to detect the disease. From the standpoint of hygiene they demonstrated the necessity of taking precautions against the tuberculous virus, whatever might be its origin.

Relations of Human and Bovine Tuberculosis and Tubercle Bacilli.—Dr. Johannes Fibiger and Professor C. O. Yensen of Copenhagen, Denmark, gave the results of comprising studies on the virulence of the bacilli, their morphology, and biology. The virulence of bacilli upon cattle was tested from twenty-nine cases of tuberculosis in man and upon rabbits from twenty-two cultures, eighteen isolated from man, four from cattle. Morphological studies of bacilli were made from fifteen cultures from man and thirteen from cattle. The characters of growth of twenty-nine cultures from man and from cattle were compared. The chemical reactions of bacilli from thirty-two cultures in glycerin bouillon were tested. The growth of bacilli from thirty-six cultures on media free from albumin were studied. Summing up the results, the authors could not admit a sharp separation between the ordinary two well-known types, though it was true that the majority of cultures isolated from cattle possess the qualities described as peculiar to "typus bovinus," and the majority of cultures isolated from human sputum correspond to the "typus humanus." There were some cultures, however, that must be considered as transition forms, having some of the characteristics of the bovine and others of the human type.

Human and Bovine. Tuberculosis Treatment by Different Kinds of Tuberculin.—Dr. Nathan Raw of Mill Road Infirmary, Liverpool, read this paper, the special objects of which were (1) to attempt to classify more easily the various tuberculous lesions of the human body, and to investigate the origin of infection, and (2) to consider the effects of treatment by different varieties of tuberculin, prepared from various sources. Up to the present time it had been the almost universal practice to classify all tuberculosis as of one common origin, to adopt the doctrine of "the unity of tubercle." Robert Koch, in his last authoritative lecture in 1901, said that "human and bovine tuberculosis were distinct and separate diseases, and that bovine tuberculosis, if conveyed to man, could not set up generalized tuberculosis in the human body." Prolonged and careful experimental research had demonstrated beyond doubt that the contention of Koch was right when he affirmed that human and bovine tuberculosis were not identical, but it had been demonstrated that he was in error when he said that bovine tuberculosis could not be communicated to the human. During the last fifteen years the speaker had had the opportunity of observing 5,000 cases of tuberculosis, and of this number, over 3,000 had died in the hospital. He said that he had no reason to modify his views set forth in 1903, viz., "That human and bovine bacilli were divisible into two distinct types of a common species, (1) typus humanus and (2) typus bovinus." The human body was susceptible to both forms of tubercle. The results of his investigations showed (1) tubercle bacilli of the typus humanus produced (*a*) pulmonary tuberculosis; (*b*) ulceration of the intestines; (*c*) tuberculous laryngitis. (2) Tubercle bacilli of the typus bovinus produced (*a*) tuberculous peritonitis; (*b*) tuberculosis of lymphatic glands; (*c*) acute miliary tuberculosis; (*d*) tuberculous joints; (*e*) tuberculous meningitis; (*f*) lupus. The differentiation of the clinical manifestations of tubercle had a most important bearing on the treatment. He believed that tuberculin was a necessity to a thorough eradication of the disease from the blood, and to the production of an artificial immunity.

Koch's Tuberculin R., or the new tuberculin, had proved of little value in the treatment of pulmonary tuberculosis, although it was of the greatest value in treating all infections of a bovine origin. In the treatment of the human infections, such as pulmonary tuberculosis, a tuberculin prepared from bovine sources was necessary. It was his firm opinion that pulmonary tuberculosis was the direct result of inhaling air containing tubercle bacilli, or in some cases of absorbing them through the alimentary tract; he was also convinced that when tuberculosis was eradicated from dairy cows it would be a rare event to see a case of surgical tuberculosis in the human subject.

Studies of Tubercle Bacilli from the Tissues of Special Forms of Primary Cervical Adenitis in Man, with Particular Reference to Intermediate and Atypical Varieties of Bacilli.—Dr. Charles W. Duval of Montreal based his paper on the study of atypical forms of the tubercle bacillus isolated directly from the tissues of four cases of primary cervical adenitis. The clinical picture in each case was the same, and the autopsies showed primary lesions in the cervical region and acute general miliary tuberculosis. Pure cultures of the tubercle bacillus were recovered directly from the cervical pus at the time of surgical intervention. Of the four culture studies, one corresponded to the bovine tpe and another to the human type. The two other cultures were intermediate or atypical forms. One was perhaps a modified bovine strain, the other might have been an avian type modified by a sojourn in man. The cultures had been carefully studied and compared with well known avian, bovine, and human types for a period of over two years. The work treated of the morphology, cultural peculiarities, histopathological lesions, and animal experiments on rabbits, guinea-pigs, rats, pigeons, and chickens. The Theobald Smith glycerin bouillon reaction was critically studied.

The Intertransmissibility of Tuberculosis.—Dr. Charles F. Dawson of the Delaware College Experiment Station, Newark, presented this paper, in which he said that if Koch's idea in regard to the intertransmissibility of human and bovine tuberculosis were correct, sanitary measures restricting the sale and movement of tuberculous animals and their products were unnecessary and were harmful to the cattle industry. More important still was the probable removal of apprehension concerning diseased animals and their products upon the public health. It was generally admitted that bovine tuberculosis was becoming more prevalent, and in proportion as it prevailed did it become a menace to public health. Statistics did not give a true idea of the extent of the prevalence of bovine tuberculosis. It was generally only the herds in which the disease was supposed to exist that were tested. In non-suspected herds it was found that as high as 26.4 per cent. of the cattle were infected in the State of Massachusetts. Experiment station showed that in suspected herds the percentage affected was 35.6, while in non-suspected herds only 9 per cent. showed infection. Tuberculosis in swine was becoming more prevalent and was found in swine fed on dairy refuse, in those which fed after dairy cattle in the field and in those which had access to the manure pile. A tuberculous cow would infect her calf if she had tuberculosis of the udder, or if she were passing tuberculous bacilli in her feces. Tubercule bacilli remained alive in milk and butter for several months. Numerous investigators had shown that the various types of tubercle bacilli might be changed in their morphology and pathogenesis by a sojourn in the bodies of different animals. Non-virulent races were made more virulent, and virulent races were made less virulent by the above treatment. It was at least plausible that the bovine tubercle bacillus should be considered pathogenic for man. Numerous cases had been cited where persons had been accidentally inoculated with the bovine bacilli and developed in some cases fatal tuberculosis, showing that the bovine bacilli were capable of producing the disease when inoculated into man.

Dr. M. P. Ravenel of Madison, Wis., said that a correct solution of this problem was important, because even if the number of deaths from bovine tuberculosis was as small as was estimated, it was not a negligible quantity. All agreed that the human type of the tubercle bacillus had not been found in cattle. It would be interesting to know how the types became differentiated. He assumed that cattle had greater resistance and were only susceptible to types having greater virulence. Only a highly virulent type was retained, the bovine system filtering out the weaker bacilli. This was the best explanation he could think of, and as a corrolary it followed that the filtration was not absolutely exact. Some animals retained more virulent types, others less virulent ones, and so on down to the feebly virulent human type. Like Professor Woodhead, he thought that changes of type could take place; he had inoculated bacilli of the bovine type and afterward found them like human bacilli. In the sputum of cows he had found bacilli very much resembling the human bacilli. It was well known that bacilli could pass through the intestinal walls without leaving any trace of their passage. They could do this in from two and one-half to four hours in sufficient quantities to cause the disease. In some feeding experiments with monkeys it had been shown that animals that had no intestinal disease showed large involvement of the lungs. This had been repeated many times, and the evidence was strong that the bacilli had penetrated to the lungs through the intestine, the lymphatic and the thoracic duct. It had been shown that most cases occurred in children, and this pointed to the intestinal tract as the portal of entry. In children fed on milk known to contain tubercle bacilli a striking number had died of tuberculosis. In his opinion, it behooved us to take every precaution to prevent the contamination of the milk, as he did not consider the number of cases of tuberculosis due to the bovine type of bacillus to be insignificant.

SECTION ON CLINICAL STUDY AND THERAPEUTICS.

Second Day—Tuesday, September 29.

Comparative Importance of Treatment in Sanatoria near at Hand, and an Entire Change of Climate.—Dr. F. I. Knight of Boston in this paper said that while the earlier treatment of tuberculosis had aimed at the relief of the symptoms, that the modern treatment was directed toward increasing the bodily resistance of the individual affected so that he might make a better fight. The sanatorium simply supplied the surroundings in which to develop the most efficient hygiene, mental, and moral attitudes, while supplying a proper climate. Climate had to be considered in every method of treatment, since even the patient at home had the climate in which he had always lived. Therefore, it was not possible to compare abstractly sanatorium treatment and climatic treatment. But if there was to be a choice between sanatorium treatment near home and a life without medical restraint under radically changed climatic conditions, the choice would be for the former. As a rule, sanatoria gave better regulation of the patient than any home constraint, and aimed to supply a humidity, atmospheric pressure, sunshine, and wind velocity adapted to give the maximum stimulation to each patient. Sometimes it was necessary to provide a radical change in meteorological conditions in order to change the factors of metabolism, but the relative value of the climatic factor would be determined only by a careful comparison of the statistics of observations made under similar conditions in different parts of the world.

Dr. C. T. Williams of London read a paper on the same subject. He said that as a rule the sanatoria, by controlling the amount of brain work and bodily exercise, caused at least a temporary improvement in nearly every case. Further, they taught that obedience to orders was the only road to improvement, and they educated the patients in hygiene. These effects were most marked in Eng-

land in the laboring classes. He looked forward to the education of the people until wholesome dwellings would be demanded by all classes. It required a long time to infuse a love of fresh air into the men and women who had been brought up without it, but the children were more hopeful pupils. At home open-air treatment was possible, but it was difficult to attain, for the fresh air necessary for the tuberculous girl was always complained of as making worse the rheumatism in the mother and the ague in the father. Climatic treatment in and of itself without hygiene was known to be the cause of recovery, especially in the instances of patients living at the high altitudes of the Andes and the Alps. One of the most remarkable and undeniable cases demonstrating the effect of climate was that of Gilbert, of a man both of whose parents had died of tuberculosis. The man himself had unmistakable signs before his first visit to the Isthmus of Panama. There he became distinctly worse and went to Quito, at an elevation of over 9,000 feet, with practical recovery in the course of six months. Seven times he had gone from lowlands to the mountains, each time becoming apparently entirely free from signs of tuberculosis. Before his last ascent there had been evidences of cavities in the lungs, marked emaciation, and a severe diarrhea, along with other symptoms that seemed to make recovery impossible, and yet he again had regained health and active vigor. But with the return of health he descended once more to the plains, and died. Hence Dr. Williams considered it proven that altitude would arrest the disease, especially in its early stages and in children, and augment the motility of the chest. Later cases he considered more favorable for local sanatorium treatment.

Dr. C. E. Edson of Denver, continuing the discussion, said that the essential aids in the cure of pulmonary tuberculosis were outdoor life for as nearly twenty-four hours in the day as practicable, sufficient food, and proper rest. That climate was most favorable which permitted or induced an outdoor life. A change of climate would be of advantage to a patient if thereby he was attracted to lead a life in the open air with ease, safety, and economy of vital expenditure. The accompanying change of scene might be expected to act advantageously in an individual way. In making any proposed change of climate, the accommodations in the new region and the possibilities for medical care should be considered. If appropriate care could be had in the better climate as well as at home, the change should be advised, but if the financial, social, or domestic circumstances of the patient were such that he could not in the new climate secure proper and sufficient food, accommodation, care, and attention, or if his mental attitude was such as to make separation from home inadvisable, change of climate should not be encouraged. It needed more than climate to cure.

Diagnosis and Treatment of Early Cases of Tuberculosis.—Dr. Lawrence F. Flick of Philadelphia held, in this paper, that tuberculosis was primarily a lymphatic disease, to be diagnosed by reaction and enlargement of the glands. Immunity might follow lymphatic tuberculosis, or the bacilli might be filtered out in the lungs—the only portion of the body through which the entire mass of the body passed in each cycle, and before it went to the rest of the body after receiving the lymph stream. He said that the apices of the lungs, along their posterior borders, were primarily affected, though the signs seemed to develop more frequently at the right apex. At that stage the diagnosis was not easily made. When the patient developed cough, night sweats, and fever, the case was already well advanced. Any ill health or loss of strength should suggest tuberculosis in persons who had been exposed to contagion. The subjective symptoms of early tuberculosis of the lungs might be cough, hypersecretion of mucus, loss of appetite, malaise, and hypersensitiveness of the nervous system. The objective symptoms were rise of temperature, disturbance of pulse rate, and dilated pupils. The physical signs were slight bronchovesicular breathing over the affected area, a pleuritic rub on expiration, increase in tactile fremitus and vocal resonance, slight bronchophony, and impaired resonance. The physical signs should first be looked for over the back in a circumscribed area. Tuberculosis was still early, both in time and in progress, so long as it was limited to one lobe of one lung, or even a whole lung, provided there was not much tissue destruction. The symptoms in the more advanced stage usually were malaise, gastric disturbance, some sense of shortness of breath, a sense of physical incapacity, cough, expectoration, chilliness or a sense of heat, and loss of appetite. The physical signs were those of bronchial breathing, prolonged expiratory murmur, pleuritic rub, increase in tactile fremitus and vocal resonance, feeble bronchophony, and impairment of resonance. When the infiltration was dense or there was secondary infection, the symptoms all became more marked and dullness on percussion appeared. Later cavity signs appeared. Absence of tubercle bacilli from the sputum should not weigh too heavily against the diagnosis. The treatment of early tuberculosis was the simple life, proper food, fresh air, and medication to restore the body to its physiological functions. Recovery did not mean sterility in relation to the tubercle bacillus, but an arrest in the process of destruction and a restoration to physiological health. In the more advanced stages, with a deficit in the physiological capacity of the organism, more heroic treatment was necessary, in the form of bed and complete rest, followed by gradually increased exercise. The diet should be suitable to the patient, perhaps one solid meal of beefsteak, fresh vegetables, and fresh fruit, and then milk and raw eggs with fruit and nuts between times. It was very important that the patient should have sufficient fresh air. If he could not live outdoors, he should be in a room with cross ventilation. Drafts could do him no harm if he was properly clad. He considered drugs useful. Iodine used by inunction was his choice. Elimination of poisons and microorganisms should be encouraged. The disease could be treated at home in any climate successfully. The home treatment prepared the patient for after life. When proper discipline could not be attained at home, the patient should be sent to a sanatorium in the climate in which he was accustomed to live. After sanatorium treatment had restored the patient to physical health, a course of home treatment should be instituted to teach him to live at home and keep well.

Dr. Lopez of Mexico said that he considered the high altitudes known to the Mexicans, with the even range of temperature all the year round, the best to produce physiological changes and greater efficiency of the blood.

Dr. Pottenger of Los Angeles said that he considered the object of treatment was to produce immunity against the tubercle bacillus. No one climate was necessary for the patients, and 95 per cent. of the patients must get well at home or not at all. The keynote to the treatment was intelligent guidance by a physician, and that was necessary everywhere, for rich and poor, in health resorts and at home. In the early diagnosis he thought that we had very much to learn, for even now infection might be present for years before an open outbreak of the conditions was recognized as tuberculosis.

Dr. Woodcock of Leeds said that one great objection to sanatoria was that while they put the man in good physical condition, they so changed his ideals that afterward he could not live in quiet at home.

X-Ray Examinations in Pulmonary Tuberculosis.—Dr. T. H. Williams of Boston emphasized the points made in his paper of the previous day that the diagnosis of tuberculosis was one of the most serious that had to be made by the practitioner. He might err by failing to make the diagnosis, thus exposing his nearest friends to his disease, or by thinking the condition present when it was not, thus unduly alarming the patient and putting him

to undue rearrangement of his affairs. The *x*-ray in aiding in this diagnosis was of great value, and was most useful in the conditions where it was most needed, in the early cases. If on examination there was found a shortened excursion of the diaphragm, a displacement of the heart toward the affected side, and an increase in density at one apex, and if these changes persisted on a second examination, some two weeks later, the diagnosis of tuberculosis was very probable. On the other hand, if two examinations were both normal, it was better not to make the diagnosis of tuberculosis except on the grounds of the strongest evidence. In later cases the *x*-rays determined calcified scars and central areas of consolidation that could not be determined otherwise. While the *x*-ray examinations were not infallible, they added to our knowledge of the conditions in the thorax and gave fuller, more accurate, or earlier information than the older method.

Dr. Henry Hulst of Grand Rapids read a paper on the same subject. He thought the value of the *x*-ray examination was dependent on the quality of the transformer used to make the rays visible, whether fluorescent screen or photographic plate, and the sensitiveness of the eye of the interpreter. He thought Williams' sign of limitation of the excursion of the diaphragm was not always present in tuberculosis, and when present was not always a sign of tuberculosis. He considered the value of the *x*-ray examination dependent on its positiveness and the completeness of its evidence. And for this the plate was better than the fluoroscopic examination. He got the best results from soft tubes and short exposures taken while the patient held his breath.

Dr. Edward Rist of Paris followed with a paper on the same subject. He considered that as yet the *x*-ray examination was not on a par with percussion and auscultation, principally because the radioscopic work was relegated to a man who devoted his time to *x*-ray work and was not versed in the possible conditions in the lung that called for interpretation. Yet fluoroscopic examinations were always a help in the interpretation of the facts obtained by percussion and auscultation. The post mortem examination and the fluoroscopic examination both regularly showed that the lesions in the lungs were more extensive than had been anticipated after percussion and auscultation. Moreover, tubercle bacilli were found repeatedly in the sputum of persons who were not suspected until the time of the fluoroscopic examination. He thought that rapid photographs taken with a short exposure gave the best results.

Dr. Minor of Asheville said that eight years of experience had led him to the belief that the *x*-rays should always be used in diagnosis, although he did not consider that they would aid in establishing a very early diagnosis. In technique he always started with a tube so soft that the fluorescent screen was dark, and then by means of a series spark gap increased the penetration until he could just see through the tissues, the work being done in a dark room efficient for the developing of photographic plates.

Dr. Leube of Würtzburg said the value of the *x*-rays was greatest in the doubtful cases to relieve the patient's mind if the examination was negative. He did not consider, however, that a negative finding should satisfy the physician, as even then there was still a possibility of the existence of tuberculosis.

Dr. Ritz of Paris thought that the extent of the lesion and the stage of development could be told better by the fluoroscope than by auscultation and percussion.

The Value of Hemoptysis as a Symptom of Early Tuberculosis.—Dr. J. M. Anders of Philadelphia read this paper. He said that the forms of hemoptysis met with in other diseases than tuberculosis usually permitted a clear discrimination. The hemoptysis occurred in the early cases of both the acute and the chronic forms. In acute tuberculous pneumonia, hemoptysis might be the first symptom to arouse suspicion of the true nature of the process. Initial hemoptysis in acute tuberculous bronchopneumonia was comparatively rare. This form might supervene, however, during the course of chronic pulmonary tuberculosis, when it was not uncommonly ushered in by blood spitting. In fibroid phthisis the symptom was rare, but when it did occur the hemorrhage was often copious. In the largest and most important group, chronic ulcerative phthisis, hemoptysis rarely occurred in cases so slight as to defy detection either by a physical or an *x*-ray examination. The importance of inquiring particularly into the previous history for various forms of perversion of the general health could not be too strongly emphasized. Cases of hemoptysis in which all clinical and laboratory findings were negative were still to be regarded as tuberculous until disproven by the tuberculin test, or otherwise. In 3,500 cases, approximately 10 per cent. manifested hemoptysis at the very commencement of the disease.

High Altitude Treatment of Phthisis, with Special Regard to Febrile Conditions.—Dr. O. Amerin of Arosa, Switzerland, showed that in the high altitude of his town tuberculous patients had marked improvement in their fever in all stages of the disease. The tendency to hemorrhage was no contraindication to the high altitude, except when there was increased blood pressure or a pulse rate exceeding 120. Cases of surgical tuberculosis were also improved by the high altitude.

Diet in Tuberculosis.—Professor Irving Fisher of Yale University, in this paper pointed out that the diet employed in sanatoria was unscientific and extremely variable. With important exceptions the diet was the same in sanatoria as in neighboring boarding houses. The variation in the number of calories was from 2,100, sufficient if no work was done, to 5,500, an excessive amount under any circumstances, which must strain the body economy and do harm even in health. It was concluded that 3,000 calories, of which 10 per cent. should be in the form of protein, were amply sufficient. Protein excess was injurious on account of the intestinal putrefaction. There was a strong tendency now against an excessive meat and protein diet.

Dr. H. M. King of the Loomis Sanatorium, Liberty, N. Y., gave a summary of the diet at that institution. He said they no longer considered milk and eggs a specific cure for tuberculosis, but the patient needed a mixed diet with distinct mastication of his food. He thought overfeeding harmful. They had recently introduced a trained dietitian and her assistant in place of the regular cook and had reduced the quantity fed from 3,900 calories to 3,100 with about 130 grams protein, 110 grams fat, and the balance carbohydrate. They used oleomargarine in place of cooking butter, and, after separating the milk, used the cream for cereals, coffee, etc., and the separated milk for drinking. This new régime had diminished the digestive disturbances very greatly and given gains in weight for most of the patients, though a few had lost. The cases under treatment were in all stages, half of them being advanced. All the patients were on carefully prescribed exercise or labor of some kind.

The Opsonic Index in Certain Tuberculous Infections.—Dr. T. W. Hastings of New York City read this paper. He considered the variations found with tuberculous individuals and with normal sera and in patients under and not under tuberculin therapy. He noted the inconstant occurrence of a low index in tuberculous infections; in ten pulmonary cases the index was below 0.6, regardless of the condition. The indices therefore did not correspond to the clinical condition and were not to be used as guides to inoculation. To establish a pathological variation, the safe plan was to estimate indices two or three times a week for two weeks.

The Opsonic Index in the Diagnosis of Pulmonary

Tuberculosis.—Dr. G. P. Sanborn of Boston presented a detailed study in the variation in the index in a case of pulmonary tuberculosis, under conditions of rest, moderate activity, hard work, and after inoculations with tuberculin (B. E.). The duration covered a period of two months, determinations being made according to Wright's methods, from one to three times a day during most of this period. The aim was to gain data on which to base specific treatment, from the study of the degree of autoinoculation that the patient was subject to from his own activities. The study showed that rest and light work might be compatible with a repeatedly normal index; that hard work might produce an elevation in the opsonic power, and that the effect of exercise and of tuberculin on the index evidently corresponded, suggesting similarity of stimuli. The application to diagnosis depended on the change following exercise, which should be varied to suit the case. The determination of the opsonic index gave less discomfort and greater accuracy than the old tuberculin test, avoided the conjunctivitis of the Calmette test, and gave greater accuracy of localization than was possible with either, or with the von Pirquet reaction.

The Accuracy of the Tuberculo-Opsonic Index and Its Value as a Control to Tuberculin Treatment in Pulmonary Tuberculosis.—Drs. H. M. T. Kinghorn, D. C. Twichell, N. M. Carter, and Mr. F. W. O. Werry of Saranac Lake presented this communication. An attempt was made to determine the mean error of a single observation as obtained from series of observations by three all equally accurate observers. This error was determined to be plus or minus 14. They endeavored to get a general view of the effect of the doses of tuberculin on the opsonic indices of the patients. They followed the slow progressive method of dosage according to Trudeau, the drug being given at intervals of three or four days, and at longer intervals when large doses were reached. They did not control the doses by the opsonic index according to Wright's method, but critically examined the effects of the doses on the index. They found that the index was raised by the injection of tuberculin; that in the majority of the tests negative phases occurred, followed by positive phases; that when they gave the drug at intervals of three or four days, or when doses of one-quarter the usual strength were given, when the index was still low, the index was rarely depressed still farther, but a positive phase at once set in. That in only 19 per cent. of the cases had the positive phase not ceased before the next injection was given. They thought that while it was quite impracticable to use the test each day on each patient on account of the time required, yet the test had showed itself of value in regard to spacing the doses. They thought the aim of the tuberculin treatment was to produce tuberculin immunization rather than merely to keep the index high, and that there was greater advantage in getting the patient able to stand large doses than in keeping the index high by small doses.

The Tuberculo-Opsonic Index in Diagnosis and Treatment.—Dr. Mary C. Lincoln of Chicago said in this paper that she had found variations of 0.3 to 0.4 in slides that should yield the same count, and therefore no rise or fall of less than 0.4 should be considered a change in the index. Moreover, the index did not follow the dilution of the serum. In comparative tests of the index, von Pirquet's skin test, and Calmette's conjunctival test, there was an agreement in 80 of the series of 200 cases, and the two latter agreed in contrast to all three in 605. The more advanced the disease the less was the reaction as a rule.

Dr. J. von Szaboky of Budapest-Gleichenberg presented a paper on the same subject, which was read in abstract.

The Application of the Cutaneous and Conjunctival Tuberculin Reactions in the Diagnosis of Tuberculous Infections.—Professor A. Calmette of Lille read this paper. He said that 92 per cent. of tuberculous patients gave positive reactions to the conjunctival test. Of clinically suspicious cases, 57 per cent. were positive, and of apparently healthy people, 17 per cent. were positive with the same test. Of 55 cases with positive conjunctival reactions not suspected of tuberculosis, which came to autopsy, macroscopic tuberculous lesions were detected in 49. In over 6,000 cases tested, the only complications noted were: In 3 phlyctenular keratitis, in 20 conjunctivitis, and in 72 a reaction prolonged beyond three weeks. In no instance did graver disturbances occur. Early reactions were observed most frequently in suspected tuberculosis, and late and slight reaction in well-developed cases. Cachectic and hypertoxic infections reacted very feebly in conjunctival, cutaneous, and subcutaneous tests. The eye test almost always revealed active foci, but was negative in the case of simple carriers and in patients with healed lesions, who often reacted to the skin test. Repeated instillation seemed to produce immunity in about 5 days, which disappeared in about 25 days. For children under one year the cutaneous test was to be preferred as the more convenient and inoffensive. In adults the number of positive results following the skin test was so great that it could not be used for early diagnosis, so that the eye test was to be preferred both in children over one year and in adults.

Observations on the Cutaneous Tuberculin Reaction in 200 Children Examined Post Mortem.—Dr. C. von Pirquet of Vienna gave the results of his experience with the cutaneous reaction to tuberculin. Koch's old tuberculin was used. The conjunctival reaction of Calmette was not satisfactory in young children on account of the difficulty in making equable tests in struggling children. Of 200 cases, some suspected and some not, 68 were positive and 66 of these showed macroscopical tuberculous lesions at autopsy, and one of the other two had a pleuropericardial adhesion. Therefore, every positive reaction showed the presence of active tuberculosis. The absence of reaction occurred in all cases without tuberculosis and in several cases with tuberculosis, particularly in older children, when the test was made only a few days before death, in some cases where the tuberculosis was complicated by measles, and in some other cases. In measles existing at the same time as tuberculosis, the cutaneous reaction was negative during the first week, but in the later weeks of measles the test might be positive. The skin reaction allowed of quantitative estimation. A marked reaction indicated great danger to life if the patient was under six months of age. In the older children the reaction did not indicate such a serious outlook.

Conclusions from 1087 Conjunctival Tuberculin Tests by a Uniform Method.—Dr. E. R. Baldwin of Saranac Lake had collected reports from 40 clinicians to whom the same tuberculin had been sent with eyedropper and directions to follow a uniform method of testing and recording results. All the tests were made inside of a period of three months. Of the tuberculous cases, 70 per cent. reacted positively. Severe reactions occurred in more than 2 per cent. of the cases. He concluded that the conjunctival test performed with weak solutions by a single instillation had some value in confirming the presence of tuberculosis in the early stages. Repetition of the test might be misleading. The test was unreliable for prognosis. Used with proper precautions, danger to the eye was slight and need not preclude the test when other methods were inapplicable, as when fever was present.

The Ophthalmoreaction to Tuberculin.—Dr. Fernand Arloing of Lyons said that in the use of the ophthalmic reaction, if the first reaction was negative, there might be a positive reaction to the second or third instillation. A previous ocular reaction was frequently revived by the cutaneous or subcutaneous injection of medicinal doses of tuberculin, but this did not contraindicate the employment of the two procedures in the same person. A previous use of tuberculin had a very variable effect

on a subsequent ocular test. As the result of animal experimentation he concluded that the ocular reaction to tuberculin occurred in individuals impregnated and sensitized by a toxin of any kind. The test had not proved itself superior to the serum agglutination which had the advantage over the ocular reaction of being absolutely harmless, more constant, and more delicate; that the ophthalmoreaction was an indication rather of the degree of intoxication to the organism, while the serum reaction revealed the forces available for defense against infection.

The Application of the Differential Cutaneous Reaction in the Diagnosis, Pathology, and Therapy of Tuberculosis.—Dr. L. Detre of Budapest described his differential cutaneous reaction. It was a modification of von Pirquet's reaction, consisting of the application to the skin of three different substances at the same time—concentrated old tuberculin, filtrate of a culture of human tubercle bacilli, and filtrate of a culture of bovine tubercle bacilli. The cutaneous reaction was an indicator of the sensitiveness of the organism. The cases could be divided into those which were positive to the human and negative to the bovine toxin, and *vice versa*, and the author distinguished a dominant papule and a concomitant papule. The difference between the two was sometimes very slight. Investigations showed that the cutaneous picture remained the same qualitatively after repeated examinations; that a human case always remained a human case; that when both toxins were injected subcutaneously the subjects showed a greater tolerance for a toxin which corresponded to the concomitant papule, while they were exceedingly sensitive to the dominant filtrate. He showed that more than 90 per cent. of the cases of pulmonary tuberculosis exhibited a preponderance of the human reaction, whereas in the visceral and surgical cases in adults the bovine reaction might be demonstrated in one-third to one-half of the cases. By means of the systematic employment of the differential cutaneous reaction, it was possible to immunize a patient with greater ease and certainty than without it. The technique was simpler, the results objective and more certain, and more easily perceived than the results of the opsonin method.

Third Day—Wednesday, September 30.

The Treatment of Tuberculosis by Tuberculins, and More Especially by Beraneck's Tuberculin.—Professor E. Beraneck of Neuchatel, Switzerland, showed that it was possible to confer upon inoculated animals marked resistance to experimental and natural tuberculosis. The difficulties encountered in these attempts at vaccination were due to the biochemical character of Koch's bacillus. Although the tubercle bacillus might act as a vaccine, it could not be used in its natural state in the treatment of a patient with tuberculosis. Here it was necessary to use the toxins either excreted from the body or constituting the substance of the bacillus, and that the immunizing properties of the tuberculin toxins did justify the utilization of these toxins in a specific treatment of tuberculosis.

The Filtered Bouillon of the Bacillus of Human Tuberculosis as an Agent in the Specific Treatment of Human Tuberculosis.—Professor G. Denys of the University of Louvain, Belgium, described his product as the liquid obtained by filtering through a porcelain filter a culture of the bacillus of human tuberculosis, fully developed in bouillon. This product was used without further treatment by heat or chemicals, and was equivalent to the diphtheria and tetanus toxins from which the antisera were derived. Subcutaneous dosage in tuberculous patients produced reactions analogous to those of other tuberculins: Cutaneous inflammation at the site of the puncture, general rise of temperature, nervousness, malaise, weakness, loss of appetite, etc., and specific phenomena in the return of general symptoms or the appearance of new ones. Great variation, from 0.0001 to 0.000001 gram and less, in the dose was necessary to produce these effects. The writer was convinced of the possibility of curing tuberculosis by this means by causing large doses, 0.1, 0.5, or even 1.0 gram, to be tolerated without appreciable injury to health. The writer was convinced of the necessity of avoiding all strong or moderate reactions in immunizing the patient, and of tolerating only exceptionally, light reactions. In general, he began with doses of 0.00000005 grams for afebrile patients, and 0.0000000005 for even slightly feverish ones. He never injected during or just after a reaction, but waited one or more days, and never increased the dose if there was any reaction whatever. In general, the adaptability to the injections and improvement went hand in hand. By this treatment he attained almost certain cure in close tuberculosis of the lungs; the more complete results were with the less advanced lesions. He also found a large proportion of cures by this bouillon filtrate in pleurisy, laryngitis, enteritis, peritonitis, adenitis, osteitis, arthritis, cystitis, etc., and got failures in the rapidly advancing cases, probably from lack of time to immunize the patient. These results were attained without sanatorium help, but other forms of treatment were not excluded.

Human and Bovine Tuberculosis, with Special Reference to Treatment by Different Kinds of Tuberculin.—Dr. Nathan Raw of Liverpool read this paper. He thought that the two types of tubercle bacillus recognized as human and bovine were distinctly different strains, and that both might cause lesions in the human body. He did not think that all of the tubercle bacilli obtained from man were of the human type, but that one-tenth of the human lesions were due to the bovine type of bacilli. The human type injected into cattle might produce lesions of great or little virulence. He considered that the human body had become tolerant of the bovine type from the consumption of contaminated milk and meat for generations. He thought that the bovine type affected the so-called surgical portions, whereas the human type affected the lungs most often. The lungs might become infected either from the inhalation of the germs directly or by secondary infection from the cervical or abdominal lymph glands, or from the blood stream, as in acute miliary tuberculosis. Of these the aerial infection was the most common. That the bovine infection in the lungs gave a more active process; that the surgical lesions due to bovine infection came in most cases from milk infection in infancy, and might lie dormant for years. He considered treatment by tuberculin very valuable, but that the two types should still be distinguished. That the pulmonary tuberculosis should be treated by the bovine tuberculin, and the surgical tuberculosis by the human tuberculin, giving each the stimulation of the opposite but allied type of bacillus from that which was the cause of the lesion. That to attain cures the lesions should be small; that in general tuberculosis little effect could be expected, and in the young response was better than in the older patients; that concurrent diseases, such as nephritis, seemed to interfere with the treatment by tuberculin. Glands of the neck gave many cures, but if suppuration had set in the tuberculin had no effect. Lupus gave very satisfactory results apart from all other treatment; that joints did well in sinus cases, but anchylosed joints did not as a rule show any improvement. Peritonitis was cured in all the cases. In meningitis some benefit was seen, but most of the cases came to treatment late. He had never seen bad effects from the treatment.

Dr. Pottenger said that he had been using bovine and human sera for three years, and considered those used different, giving different degrees of reaction. He said that one would increase the toxicity of the patient, and the other relieve it, and that one would give local reaction when the other did not; that at times after using one type for a while the other gave better results. The acute processes did better with bovine and the chronic with human tuberculin. He believed tuberculin of one type when injected stimulated antitoxins of the allied type.

Dr. Phillip of Edinburgh said that he had found only good to come from the use of tuberculin in routine treatment, but that the results were limited anatomically and physiologically. Anatomically in such conditions as pulmonary tuberculosis, where, after the process had progressed to a certain point, the adhesions to the uncollapsible chest wall prevented further scar formation; and physiologically, limited by the inability of the body to cope with extensive and generalized lesions. He now used Beraneck's serum because he had found it less toxic and not less efficient than others.

Dr. Denys said that he used human bacilli exclusively because he believed the typus humanus was the cause of the lesions. He did not believe that mixed infections warranted the use of antistreptococcus sera with the tuberculin because he had tried the killed bouillon cultures with no effect.

Dr. Beraneck also did not believe in the efficacy of the antistreptococcic sera in the cases of mixed infection.

Antibacterial or Antitoxic Immunization in Tuberculin Treatment.—Dr. E. L. Trudeau of Saranac Lake read this paper. He said that there were in the tuberculin treatment two theories as to the method of action of the tuberculin: The vaccination theory, which claimed to bring about by injections a specific immunity to the tubercle bacilli, and the toxin theory, which aimed merely to produce by steady slow progression in dosage, the greatest degree of tolerance or immunization to the poison of the bacillus. Under the first concept, the specific immunization to the bacillus, were Koch's later attempts at producing an immunizing tuberculin, both local and focal reactions being looked upon as useful in the production of the specific immunity to the bacillus; also the work of Wright and his vaccine treatment, guided by the reading of the opsonic index. Under the toxin immunization theory, of which Denys and Sahli were the most brilliant exponents, the main feature of the treatment was to produce by progression in dosage the highest tolerance possible to the tubercle bacillus, considering reactions and all constitutional disturbances, as not only not desirable, but to be avoided. Certainly the violent reactions were not helpful, and the mild reactions were still of doubtful value, for as good results followed the absence of even the focal reactions. Dr. Trudeau believed in an immunity that was principally at least antitoxic as produced by treatment; and tuberculin toleration was its essential feature and best guide to dosage. On this plan, treatment tends to raise the degree of tolerance to tuberculin to the highest point attainable, by an almost imperceptible and long-continued progression in dosage; to avoid general and focal reaction, and regard them merely as evidence of intolerance; to follow no rule as to rate of increase or maximum dose to be reached, but to be guided merely by the tolerance of each patient, as shown by the general condition, whether the highest individual dose be a small fraction of a milligram or a cubic centimeter, or more. This antitoxic theory did not explain all the good results attained in the localized lesion, and so was not entirely satisfactory, but was preferred by the writer.

In reply to a question, Dr. Trudeau said that he used now Denys's filtrate, which had the advantage of not being boiled, and gave a less violent reaction. He did not believe in the theory of opposed vaccines of Dr. Raw, as all the fame that had been gained by tuberculin treatment had been in the attempt to treat the condition by an homologous bacillus.

Temporary Hypertension as a Cause of Certain Hemoptysis in the Tuberculous, and the Hypotensive Medication in Such Cases.—Dr. M. Gaultier of Paris read this paper. He believed that in a certain per cent. of the cases of pulmonary hemoptysis the direct cause of the bleeding was hypertension. This he had controlled in a number of cases by using an aqueous extract of mistletoe (viscum album), which seemed to have a prompt but lasting effect in reducing general blood pressure by action on the central nervous system, thus controlling the hemorrhage in every case. He gave .05 grams at a dose and .30 grams in the course of a day, one dose being given every two hours hypodermically, and at night morphine for sleep.

Untoward Effect Following the Use of Maragliano's Serum.—Dr. H. R. M. Landis of Philadelphia presented this communication. He found that 17 per cent. of the cases treated showed marked hypersusceptibility to the serum, shown in the suffusion of the face, cardiac oppression, rapid pulse, muscle tremors, etc., coming on promptly after the injection of the serum. He had had no fatalities. That this hypersusceptibility seemed to persist in some cases through the rest of life, and might be transmitted to the offspring. These cases differed from the anaphylactic phenomena seen in the guinea pig in having no definite time for its occurrence. All the cases had been advanced or moderately advanced disease, and were confined to bed. Ambulant cases did not seem to develop anaphylaxis; four of six cases had the serum disease.

The Maragliano Serum Treatment at the Phipps Institute.—Dr. Lawrence F. Flick discussed the introduction into America of this mode of treatment, following a paper read by Maragliano, in which he announced that it was possible to produce a specific therapy for tuberculosis and that it was possible to immunize the animal organism against tuberculosis. The Phipps Institute sent men to Maragliano's laboratory to study his methods and the methods of other men in Europe. It imported some of Maragliano's serum for use in the institute and had the serum made by the man who studied with Maragliano. The consensus of opinion of twenty members of the staff who used the serum was that it had no specific value. The cows used for making the serum were tested for tuberculosis and found free from it. They were guarded against infection and immunized by injections recommended by Maragliano. The serum given by them seemed to be as satisfactory as the imported serum. Later one of the cows died of general tuberculosis and was found very extensively diseased. The other cow was then killed, and she was found to be slightly tuberculous. This brought up the questions: Can an animal give an immunizing serum and itself not be immune? Does the withdrawal of the serum from an animal deprive it of its protection against the tubercle bacillus? The questions were not answered.

SECTION ON SURGERY AND ORTHOPEDICS.

Second Day—Tuesday, September 29.

Retroperitoneal Tuberculous Glands and Their Relations to Spinal Symptoms (Tabes Mesenterica).—Dr. Charles F. Painter of Boston read this paper. He said there were many intraabdominal and intrathoracic pathological conditions which often confused the diagnosis of tuberculosis of the spine. Any pathological enlargement of the organs of the abdomen, perinephritic abscess, aneurysm, etc., might cause more or less impairment of the movements of the spinal column and give rise to confusion in diagnosis. But among the most common of these causes of confusion were accumulations of tuberculous glands in the mesentery or behind the peritoneum. He wished to lay special emphasis upon that class of cases which fell short of tabes mesenterica and which caused spinal symptoms. A study of the anatomy of these glands would show their close relationship to the spinal column. The glands lay so close to the spine that they might erode the bone and point to the spine as the seat of the lesion. A large majority of the glandular enlargements in this region were apparently tuberculous. The finding of caseation and calcification was sufficient to establish a diagnosis of tuberculosis, and it was not necessary to demonstrate the presence of the tubercle bacillus. There was an abundance of evidence in the litera-

ture to show that the tubercle bacillus could gain access to these glands through the alimentary tract without producing any detectable lesions in the mucous membrane of the intestine while passing through it. The symptoms were pain and stiffness in the spine, and difficulty in getting to an erect position. In some cases the pain was slight or absent. The advent of the disease was slow. In some cases there might be swelling of the lower abdomen and thigh. This did not indicate disease of the psoas muscle, and did not give rise to flexion of the thigh. An examination of the spine would show rigidity, and possibly some kyphosis, but the latter was not sufficiently angular to indicate spinal disease. As the patient improved the kyphosis would diminish and finally disappear, which was not the case in spinal disease. Palpation of the abdomen might or might not show enlarged glands. The treatment was hygienic, operative, mechanical, and largely constitutional. In the main, the prognosis was good.

Dr. Wisner R. Townsend of New York said he appreciated the importance of these conditions which simulated spinal disease, and he thought the Boston school of orthopedics deserved a great deal of credit for bringing forward more information on these subjects. It seemed to him that the most important thing they had done in the last few years in regard to spinal lesions was in having made it possible more clearly to differentiate the symptoms. It was unfortunate in this class of cases that an early diagnosis often could not be made. But it was a very good thing to call attention to the fact that these conditions did exist, and that they were not as uncommon as had generally been supposed. A great many escaped observation entirely, being treated as lumbago, etc., whereas in reality they were the beginning symptoms of a more serious condition.

Dr. Charles N. Dowd of New York asked what experience the writer had had in the removal of the mesenteric glands in these mild cases. He had had experience in the well marked cases of tabes mesenterica, and had been very much surprised to find how easy it was to remove large masses of these nodes and to get a good healing. He had not had any experience, however, in operating on the class of cases referred to in the paper. Surgery surely offered a very promising field of treatment for this condition, and he wished to know whether the writer of the paper had operated upon any of the cases.

Dr. Painter, in closing, said that a good deal of work had been done on the aggravated form of these mesenteric enlargements, but he had not operated in any of the cases of the milder type. He had been unable to persuade surgeons as to the advisability of making laparotomies in these cases. On the other hand, he had seen some very serious cases, which the surgeons had considered hopeless, and in which spontaneous recovery had taken place. Therefore, the determination of what cases should be subjected to surgical treatment was still an open question.

The Surgical Aspects of Tuberculosis of the Lungs and Pleura.—Dr. Samuel Robinson of Boston read this paper. Surgery could claim little credit for the progress in the cure and prevention of tuberculosis. Not only was the history of intrathoracic surgery characterized by slower progress than the surgery of any other region in the body, but of lesions within the chest those of a tuberculous nature had been especially unyielding to surgical interference, and had given little encouragement to operators to invade this region. The literature supplied us with rather a discouraging story of tuberculous cavities drained by thoracotomy, in which the patient's general condition was at least temporarily relieved, although the course of the disease was seldom arrested. There were a few reported cases of partial or complete pneumonectomy in which the patient's life had been abbreviated either by the shock of the operation, by the existence of pneumothorax after the closure of the chest, or by collapse of the lung of the unoperated side due to injury of the mediastinum. In those few cases in which the operation could be regarded as successful, a fatal outcome had been the result, owing to the increase and spread of the disease from the remaining lobes of the opened side and to the transmission of the infectious material across to the opposite lung. The twentieth century had already witnessed an advance in the technique of intrathoracic surgery by the introduction of the negative pressure method of avoiding the dangers of pneumothorax, and also by the perfecting of the positive pressure method of obviating these dangers. The investigations of Sauerbruch, Brauer, Matas, Smythe, Greene, Janeway, Mayer, Tuffier, Seidel, and himself had proved that an exploratory thoracotomy was attended under the new methods with no greater danger than an exploratory laparotomy. Those investigators would also agree that the partial or complete removal of one or two lobes of either lung was an operation which could be regarded as attended with little danger to the patient. The latter conclusion was based largely on animal experimentation, but it was a well-known fact that the human thorax was less prone to infection and less susceptible to the dangers of pneumothorax than that of most aniamls which had been used in animal experimentation. The human mediastinum being a comparatively unyielding structure, the conditions of the unopened side of the thorax were not as unfavorable as was the case especially in the dog. Fifteen operations had been done upon the chest of rabbits without the use of any apparatus, and of the last ten operated upon eight were still living. Granted, however, this newly justified procedure of thoracotomy for exploration of partial pneumonectomy, the writer asked what could be said as to the prospects of successful surgical attack on pulmonary tuberculosis? An insufficient number of cases had been operated on since the perfecting of the new apparatus methods from which to draw any conclusions. It was to be regretted, however, that the cases most suited to operative interference were also the ones commonly recognized as promising for hygienic results, that is, those cases of isolated foci confined to one or two lobes of one lung. With the help of the *x*-ray such cases were early recognized, even before physical signs were diagnostic, but the internist would hesitate to turn such a case immediately over to the surgeon for lobe excision until he had resorted to general treatment. Having failed in the latter, the case would then be a far less suitable subject for the total excision of the diseased area, owing to the extension of the infection, to the involvement of other lobes, and even to the direct transmission of infectious material to the opposite lung. In other words, it could no longer be justly stated that tuberculosis of the lung and pleura was out of reach of the surgeon, but the question remained an open one as to whether drainage or excision of tuberculous foci in the thoracic cavity could ever result in the removal of the infection. It was at least to be hoped that the disease might be more successfully attacked by vaccine therapy and hygiene if the larger cavities of infectious material had meanwhile been excised or drained by the surgeon.

Dr. Emil G. Beck of Chicago spoke of some experiments which Dr. Opie of the Rockefeller Institute, New York, had been carrying on. Dr. Opie had infected the pleuræ of dogs with tuberculosis, and after they had developed the symptoms of tuberculous pleurisy, the pleural cavities were injected with white blood corpuscles obtained from the pleural cavity of a healthy dog after the injection of an irritant. Dogs that had been treated in this way and killed after a certain period of time showed that the pleural cavity had nearly healed, while the animals which were not treated in this manner died with the general symptoms of tuberculosis. As stated by the author of the paper, at least seventy-five per cent. of all empyemas were the result of tuberculosis of the pleura and lung, and he believed that Dr. Opie's method, if further experiments had the same results, would be one way of attacking tuberculosis of the lung. Dr. Beck also mentioned his method of treating empyema and tuberculous pleurisy by the injection of a

bismuth paste, the details of which would be given in a paper to be read by him later in the week.

Dr. Russell Bellamy of Wilmington, N. C., said the chasm between the normal and abnormal was sometimes wide, but he believed that the work done by Dr. Robinson in these ten rabbits was a tremendous step forward. Even if he was not successful to the extent of being able to attack the abnormal, his paper would be heard or read by someone who would be able to bridge this chasm, and soon surgeons would be able to approach tuberculosis of the lung as the reader of the paper had suggested.

Dr. H. Berlin of Chattanooga, Tenn., said we had been able to do something with negative pressure, and if we could get a positive pressure apparatus that was successful he thought we would be able to do much more. Lung abscesses could be opened by this method, but what could we expect in a general tuberculosis of the lung? We might be able to remove one or even two lobes of a lung, as had already been done in animals, but in what way would it benefit the patient to have this done?

Dr. Robinson said that although operations had been done without apparatus, it was impossible to say the patient would not collapse on opening the pleural cavity. The rabbit experiments had been very gratifying. In the thirty operations on dogs the operations consisted in removal of a greater or less portion of the lung, and out of the thirty operations there were twenty-one recoveries. The deaths were largely in cases where an attempt had been made to remove the entire right lung. In these operations it was absolutely necessary to have the apparatus going. If it broke, the animal went to pieces at once. By pulling the lung into the opening in the chest wall, the symptoms of collapse could be arrested. A great deal of the surgery of the chest in the last fifty years had consisted in this procedure. In his experiments with rabbits he had first begun by pulling the lung out through a small opening, but the lung tore at once, because of its delicate structure. Then a wide and long intercostal incision was made, a ligature was put around the lung root, and it was then amputated. After two operations, one day the apparatus did not work very well, and the animal seemed to do just as well. After that the apparatus was discarded. The animals were etherized, and the chest opened widely. There was no sign of dyspnea during an operation lasting an hour and a half. In the first few he was not familiar with etherizing the rabbits and he lost some of them on that account, but of the last ten operated on, eight were still alive. The question was, "Which do the human tissues most resemble, those of the rabbit or those of the dog?" He was convinced that the disastrous results in dogs was due to the mobility of the mediastinum, which was not the case with the rabbit. In the rabbit the heart seemed to occupy a greater portion of the mediastinum than was the case in the dog.

Tuberculosis of Cervical Lymph Nodes. Report of 275 Cases Treated by Radical Extirpation.—Dr. Charles N. Dowd of New York read this paper and illustrated it with numerous lantern slides. The disease was a serious one, probably with a mortality rate little below 50 per cent. when untreated. It was particularly adapted to radical treatment, and was the only form of tuberculous infection which could be eradicated without removing a single important structure. The important structures in the neck were in the soft parts, easily pushed aside, and the infection almost invariably appeared first in one group of glands. It was a form of tuberculosis not suited for medicinal treatment, and reports from sanatoriums showed that such cases did not improve under medicinal treatment. During the last fourteen years he had treated 275 cases by radical extirpation, and the cases had been carefully followed from year to year. There had been only one death in the entire series, and that was due to a secondary hemorrhage from the jugular vein. The percentage of cures was apparently about 80 per cent., with another 10 per cent. or more of improvements. Secondary operation was necessary in 16.7 per cent. of cases. Operation was usually a scar-saving procedure. By making a transverse incision the folds of skin in the neck would often almost hide the scar. The existence of hard nodules after operation was often puzzling, but it had been shown that these did not indicate tuberculosis.

Dr. E. M. Sala of Rock Island, Ill., said he had had very good results in these cases with the *x*-ray treatment. There was no question in his mind but that the *x*-ray would make these nodules disappear in a reasonable length of time. His custom had been to give them about ten minutes' exposure with a good strong light at a distance of five or six inches from the tube. He had had no severe burns at this distance. Surgery was the proper course of procedure, but where for any reason that could not be resorted to, good results could also be had from the use of the *x*-ray.

Dr. Charles H. Mayo of Rochester, Minn., said children under eight seldom required operation. The focus of infection should be eradicated, if possible, that is, the enlarged tonsils, adenoid conditions in the throat, and nasal troubles. If after such treatment there still remained for a long period enlargement of the glands of the neck, then the operation would be indicated. Later in life the bulk of these cases should be treated, not only by the removal of the local focus, if that could be done, but the removal of the glandular system as well. Treatment by the *x*-ray did leatherize the tissues, producing a great deal of sclerotic tissue. It was best to recognize only three groups of glands, a deep group on each side, and a submaxillary and submental group. If tuberculosis attacked one gland the whole group must be removed. The lymphatic system was very closely connected with the blood, and it was no farther to the lungs through the lymphatics than it was through the air passages. Recurrence took place because the entire group of glands had not been removed.

Dr. Emil G. Beck of Chicago spoke of the use of bismuth paste in the treatment of sinuses in connection with tuberculous glands of the neck. Only three cases had come under his observation which could be treated by this method, and two of those had been reported by two physicians from Mississippi who had injected the bismuth paste into sinuses which were left after operation. He had himself treated only one case, and in that case he had used it to prevent a sinus. This patient was so diseased with tuberculosis and had so many sinuses in his body that operation was not advised, but one of the glands was suppurating and ready to open. It was opened with a very small incision, the bismuth paste injected, and it healed without a sinus. Of course, it might have healed up spontaneously anyway. Where any tuberculous tissue had been left within the tract of the sinus, or where these sinuses had become infected by a remaining tuberculosis, it had been proven that all the microorganisms would disappear from the secretion in three or four days following the injection of the bismuth paste.

Dr. Dowd in closing said he had found one class of cases particularly in which the *x*-ray treatment was valuable. That was the class in which the infection was very virulent. The tissue resistance was very low. Such a patient perhaps would have the sternocleidomastoid muscle involved. The glands might be removed as thoroughly as possible, but a few weeks after operation there would be a diffuse swelling in the area of the operation. These cases were particularly unfavorable for further surgical work. Nothing would remove the tuberculosis short of the most radical possible procedure, taking out the muscle or as much as might be involved, and taking out the nerves that might be involved. That might be done for cancer, but he did not believe it wise to do it in tuberculosis. These cases did very well under *x*-ray treatment. There was also a large number of cases which would do well under *x*-ray treatment which were not of this type. But a good many

cases would also do well under any form of treatment, or under no treatment at all, and it was that fact which made it difficult to have a suitable comprehension of the subject. It was safe to say that at least half the cases would get well if we did not do anything for them. But there was a great difference between this number and the 85 or 90 per cent. who would get well if operated on as much as needed. As to operations on children under eight years of age, he believed that depended on the environment. In the tenements of New York, for instance, one would see frightful cases under eight years, and he was sure many of these cases needed operation. However, he agreed perfectly with Dr. Mayo that there were many others who would get well without operation.

Third Day—Wednesday, September 30.

Two Clinical Cases Suggesting the Surgical Possibilities in Tuberculous Meningitis.—Dr. H. P. Stites of Paducah, Ky., reported two cases of tuberculous meningitis in which he had trephined the skull and established drainage, followed by recovery. The first case was that of a child 10 years of age. A medium-sized button was removed from the skull in the temporoparietal region just above the lateral sinus of the left side. The location of the opening was suggested by the marked symptoms on the right side of the body. The membranes bulged into the wound, and a free incision was made. A quantity of serofibrinous fluid escaped, in which tubercle bacilli were later demonstrated. The child regained consciousness immediately after recovering from the ether. On the eighth day after the operation the wound was allowed to close, and alarming symptoms appeared, but they were immediately removed on re-establishing drainage. The patient recovered entirely, and was now well. The second case was that of a man 29 years of age. Here, also, tubercle bacilli were found in the discharge. Recovery as in the other case. The author believed that surgical interference would save life in many cases.

Tuberculosis of the Breast.—Dr. William Rodman of Philadelphia read this paper. This disease had been considered very rare. A study of 1,500 cases of disease of the mammary gland in St. Bartholomew's Hospital, London, had shown 1.5 per cent. of that number to be tuberculous. It occurred most commonly between the ages of 25 and 35. The pathological forms were: the discrete and confluent forms, intramammary abscesses, and acute miliary tuberculosis. Tuberculosis was rarely associated with carcinoma, the author having been able to find but five cases in the literature, and one case of his own. The discrete form was very difficult to recognize; the confluent form very easy. It was apt to be confounded with actinomycosis, syphilis, and carcinoma. The prognosis would depend largely upon whether the disease was primary or secondary; in the former good, in the latter bad. Surgical treatment consisted in curetting and excision or amputation of the breast. It remained to be shown whether anything short of amputation of the breast was a safe remedy. At the same time, that was a serious remedy, and would often be objected to by young unmarried females. In such cases it was better to perform plastic resection, and then amputation later if necessary. He believed that vaccine therapy and Bier's hyperemic method should be used only as valuable adjuncts to surgical treatment.

Dr. Carl Wirth of St. Paul, Minn., asked if the milk from any of these tuberculous glands had been examined. He had had a case where an infant had developed marasmus, and it was later found that the breast it had been nursing was tuberculous.

Mr. Arbuthnot Lane of London agreed with the author that complete removal was the most effective treatment. He wished to call attention to the fact that all these patients which he had seen suffered from autointoxication and constipation, as was the case in other forms of tuberculosis. The autointoxication had very materially lowered the resistance of the individual, and an important element in treatment was thorough gastrointestinal drainage. The practice of the older practitioners in always ordering a purge when a case was first seen was a good one.

Dr. Rodman, in answer to Dr. Wirth, said no examination of the milk had been made.

The Treatment of Tuberculous Hip Disease by Weight Bearing and Fixation by the Lorenz Hip Spica.—Dr. H. Augustus Wilson of Philadelphia read this paper. He said that weight bearing was conducive to the benefits afforded by outdoor life. Constitutional activity prevented circulatory stasis, while confinement and inactivity favored atrophy from disuse. Weight bearing without fixation, under the most favorable circumstances, might result in recovery, but with ankylosis in deformed postures. Weight bearing with the Lorenz short hip spica facilitated the employment of outdoor life, and shortened the time of treatment. In suitable cases this treatment showed a full return of function. There was rapid recovery from abscess formation in some cases, and in others slow but permanent recovery. Beck's bismuth injection should be used where there were sinuses. Sound ankylosis would be produced in cases previously confined to bed or where there was atrophy from disuse by using crutches. The muscular development of an atrophied leg often demanded frequent changes of casts, thereby indicating the benefits obtained. Weight bearing with fixation aided in securing the beneficial influences of Bier's hyperemia. Constitutional treatment and diet were important. Pathological dislocations might occur with improper position of fixation. The most favorable posture was that of twenty degrees of flexion, twenty degrees of abduction, and five degrees of external rotation. This method of treatment did not appear applicable to debilitated patients without the temporary aid of crutches. Sixty cases had been treated in this manner by the author in the last six years. The average duration of treatment was ten months.

Vaccine Therapy in Joint Tuberculosis.—Dr. Edward H. Ochsner of Chicago read this paper. Vaccine therapy in joint tuberculosis should never be employed unless controlled by careful reading of the opsonic index, and should always be associated with other recognized methods of treatment, such as fresh air, suitable food, immobilization of the joint, prevention of secondary infection, etc. If thus employed we could obtain a very considerable percentage of perfect anatomic and functional cures, because the vaccine treatment secured a healing with a minimum amount of connective tissue formation.

The Treatment of Hip-Joint Disease.—Professor Calot of Berck sur Mer, France, presented this paper, which was read by the Secretary of the Section, Dr. John T. Bottomley of Boston. To prevent erosion and destruction of the articular bone surfaces he recommended the early injection of a mixture consisting of creosote 3 parts, iodoform 7 parts, ether 25 parts, and olive oil 50 parts. A horizontal line should be drawn, passing by the spines of the pubes, and the femoral artery should be located. Then a long needle should be inserted at a point 2 cm. outside the artery and 3 cm. below the horizontal line. At 4 or 5 cm. deep the point of the needle came in contact with the anterior surface of the neck of the femur. The thigh should be put in slight flexion, abduction and outward rotation. The injections should be repeated every three to five days, nine or ten in number, and cover a space of some two months. Four to 10 c.c. of the liquid should be injected, according to age. All this time the patient must be in bed, either with extension or in a bivalve plaster cast.

Dr. De Forest Willard of Philadelphia thought the results obtained by Dr. Wilson, if carefully analyzed, were about the same as from other methods of treatment. If we could get these cases early, there was no question but that all of us could obtain good results. Fresh air and outdoor life were very important. The ambulatory treat-

ment should not be used in the acute stage. Vaccine therapy and the Bier treatment were good, but no one thing would cure tuberculosis. The same applied to injections. We could do more in conquering tuberculosis by building up the resistance of the individual than by attempting to destroy tubercle bacilli.

Dr. Russell Bellamy of Wilmington, N. C., believed climate was the most important factor in dealing with these cases. Seven-eighths of all the patients in the Hospital for Deformities in New York were from the slums of New York. He had seen splendid results from the use of the plaster spica.

Dr. Emil G. Beck of Chicago said he would hesitate to use a needle where it was possible to inject material into a vein, because death would follow in two minutes. He had proved this in experiments on guinea-pigs. He advocated the injection of the bismuth paste after opening the abscesses.

Dr. Eugene Caravia of New York advocated the use of Cuguillère's serum, which consisted of allylum sulphide 1 gram, tincture of myrrh 1 gram, and Hayem's glycerinated serum 100 grams. One hypodermic injection of from 2 to 5 c.c. was given every week. Dr. Caravia had used the serum in two cases of adenitis of the neck, one small subcutaneous tumor of the breast, one white swelling of the knee, and one periostitis of the tibia. No other treatment was used. From three to twelve injections were needed to effect a cure, which was permanent.

Dr. A. T. Cabot of Boston wished to call attention to one point in the handling of surgical tuberculous cases. Patients suffering from pulmonary tuberculosis were required to exercise care in the disposal of their sputum, but practically no attention was paid in hospitals or elsewhere to the disposal of surgical dressings from tuberculous cases. Such dressings should be immediately treated with boiling water, or some suitable antiseptic, or burned.

Dr. Tienstall Taylor of Baltimore said weight bearing should not be used in acute cases, and should be confined to hospital and sanatorium treatment, as it was sure to be meddled with if tried at home. The bivalve spica was best, because it would permit massage. Climatic treatment was very important. Vaccine therapy was also very useful. Braces and the prolonged use of traction had been very much overdone. On the other hand, he did not agree with Lorenz that early ankylosis in these cases was desirable.

Dr. Wilson, in closing, said the museums were full of specimens showing joint destruction from tuberculosis. A movable and functionating joint was always preferable when such function was not apt to be destructive to the surrounding tissues and to the health of the patient. But where there was great destruction the question came up as to whether it was better to have mobility or ankylosis. He was unable to answer the question.

Dr. Ochsner, in closing, said he wished it understood that vaccine therapy was not a cure-all; but it was a very valuable adjunct to the ordinary modes of treatment. He wished to lay special stress upon his observation, that by the proper application of vaccine therapy he had been able to reduce the quantity of connective tissue in the healing of tuberculosis. He was sure that vaccine treatment would reduce the mortality somewhat. He was sure that within the last two years he had had several cases of joint tuberculosis which came with great sinus formations and secondary infection and which would have died had they come five years earlier, before the use of the vaccines. He firmly believed that morbidity would also be reduced by vaccine therapy in conjunction with other measures.

Outdoor Treatment of Surgical Tuberculosis.—Dr. De Forest Willard of Philadelphia read this paper. Outdoor life, night and day, was as essential in the treatment of tuberculosis of bones and joints as in medical cases. Early diagnosis, with treatment by sunshine, fresh air, rest, and proper mechanical and surgical procedures would prevent and cure without deformity a large majority of cases of joint diseases—25,000 doses of pure air in 24 hours were infinitely better than 3 doses of nauseous drugs that disturbed digestion. Tubercle bacilli would die in sunshine, but thrive in darkness, vitiated air, and filth. Their growth was inhibited by cold. Cold increased the appetite, nutrition, and circulation, and encouraged exercise and sleep—color, weight, strength, and hemoglobin increased. A change from the seashore to the mountains was desirable; but 90 per cent. of joint cases were poor. Separate hospitals and sanatoria for surgical tuberculous cases were needed. They should be constructed so that the bed could be thrown, by window sashes, either indoors or outdoors, thus giving a warm room for surgical dressings and needed care. Joint cases required level ground for crutches. Tents were hot in summer and cold in winter. Porches roomy for beds, connected with private rooms or with hospital wards, open in summer, glass enclosed in winter, were far better. Children with hereditary tendencies should attend forest schools.

Dr. John M. T. Finney of Baltimore said the Johns Hopkins Hospital had been a pioneer in this country in advocating the outdoor treatment of surgical tuberculosis. In the early days of the hospital Dr. Halsted had insisted in keeping these cases out of doors. The results had been most satisfactory. Early diagnosis was very important, as many of these cases were treated at first for rheumatism.

Dr. R. W. Corwin of Pueblo, Colorado, believed that all cases of tuberculosis, surgical or otherwise, should be treated in the open air and not in the hospitals of the large cities. There were only two reasons why hospitals for tuberculosis had not been taken to the country, and these were ignorance on the part of municipal authorities and because doctors were too lazy to go out into the country.

Dr. Carl Wirth of St. Paul, Minn., asked if secondary infection of the lungs had been observed. Out of something like 4,000 cases of tuberculosis he had never seen a secondary infection of the lungs.

Dr. L. H. Montgomery of Chicago said it was universally conceded that the open-air treatment of any form of tuberculosis was desirable, whether surgical or otherwise.

Dr. Willard, in closing, said that in his experience lung tuberculosis occasionally occurred after tuberculosis of the joints, but rarely. The majority of his fatal cases were due to tuberculous meningitis, and not from secondary lung tuberculosis.

Fourth Day—Thursday, October 1.

Tuberculous Arthritis of the Hip Joint.—Dr. Stephen H. Weeks of Portland, Maine, read this paper. After reviewing the symptoms and diagnosis, he said the treatment was divided into local and constitutional. Local treatment was more important than constitutional treatment. The local treatment was divided into mechanical and operative—mechanical treatment was used in the majority of cases. The great principle of local treatment was rest to the affected joint, and this might be secured by traction and fixation, one or both, according to the indications. In considering the constitutional treatment, he said if there was one point that had been emphasized by the newer ideas on the treatment of tuberculosis, it was that everything must be done to strengthen the defences of the system against the encroachments of the tubercle bacilli. This applied equally well whether one was dealing with pulmonary tuberculosis or with tuberculosis of the joints. The salient idea was to increase the vital resistance by fresh air, sunlight, and proper nutrition. Remarkable results had been achieved in recent years in cases of tuberculosis of the various joints by an outdoor life, particularly at the seaside, and without resort to operative measures. As to vaccine therapy, all that we could say at the present time was that it might prove a valuable adjunct to other treatment.

Dr. Willy Meyer of New York said there could be no

doubt that in the last twenty-five years the pendulum had swung toward conservatism in the treatment of these cases. In the beginning of antisepsis thirty years ago almost every surgeon attacked the hip joint by means of resection. So far it had been impossible successfully to apply the Bier treatment to the hip joint. The hip joint was supplied by the internal iliac vessels, and the iliac vein could not be compressed. He had made attempts to compress the inferior vena cava. This was difficult and painful, and yet he believed this was the only solution of the problem. It might be possible to construct cups, but they would have to fit very snugly about the hip. Many links were necessary to complete the chain in the treatment of tuberculosis—and tuberculin, hyperemia, and hygienic and dietetic treatment were very important links in this chain.

Dr. John Lindahl of Denver, Colorado, said there was an important anatomic fact in connection with joint disease, and that was that the joint was supplied by the same nerve that supplied the surrounding muscles. This accounted for the spasms of the muscles in these cases. These spasms were particularly injurious at night. To control these spasms he had been in the habit of using a firm bandage applied to the thigh and hip. He had also used a canvas casing which could be buckled on. He had never been able to apply a plaster-of-Paris dressing that would control the spasms for more than three or four days, because there was always a tendency for it to become loose on account of the absorption of the fat.

Dr. Weeks, in closing, said he wished to emphasize the fact that hip joint disease was primarily a local inflammation and should be treated as such. If the disease was recognized early and treated properly, in the vast majority of instances operative interference would not be necessary.

Tuberculosis of the Bladder.—Dr. Wilhelm Karo of Berlin read this paper. Tuberculosis of the bladder was almost always a descending process, of hematogenous origin, as a rule the result of renal or genital tuberculosis. Pathologically a distinction had to be made between genuine bladder tuberculosis and tuberculous cystitis. The seat of the morbid changes in the bladder usually depended on the mode of infection. Thus in a case of right-sided renal tuberculosis the lesion was near the right ureter. The chief symptoms of bladder tuberculosis were difficult micturition, hematuria, and pyuria. The diagnosis must be confirmed by finding the tubercle bacilli, either directly in the preparation or by animal inoculation. In every case of urogenital tuberculosis the primary seat of the tuberculous infection must be determined as soon as possible by cystoscopy or catheterization of the ureters. The cystoscopic picture was not in itself absolutely characteristic of tuberculosis. Nodules were also found in nontuberculous disease. The surest prophylactic measure to prevent tuberculosis of the bladder was early extirpation of the diseased kidney before involvement of the bladder had taken place. Hence, the prognosis of bladder disease depended on whether the case was operable or not. In the great majority of cases spontaneous recovery of the bladder followed removal of the primarily diseased kidney. If the bladder did not clear up it was often because the other kidney was also involved. The most suitable treatment of cases of this kind was a systematic tuberculin-cure, supplemented by local treatment of the bladder with a weak bichloride solution. Direct surgical treatment of a tuberculous bladder was of no avail and was therefore not to be attempted.

Tuberculosis of the Bladder.—Dr. Bransford Lewis of St. Louis, Mo., also read a paper by this title. He said the points he wished to emphasize were the greater confidence and hopefulness with which such cases were now contemplated, by reason of the more scientific and exact methods of diagnosis at hand, giving early recognition and treatment of the tuberculous bladder; and the relatively greater actual success derived from these sources, as well as from the more serviceable modern methods employed. The clinical evidences were of great importance, because they attracted the attention of the physician first consulted. Persistent and apparently inexplicable frequency of urination and microscopic blood in the urine extending over a long period should arouse a suspicion of tuberculosis. Other important symptoms were pain and excessive tenderness on instrumentation. Free use of local anesthetics should be made in all examinations. Marked diminution in the bladder capacity was a characteristic sign. The crucial test was the finding of tubercle bacilli in the urine. The urine should be obtained in such a way that there would be no way of contaminating it with smegma bacilli, as it was extremely difficult to differentiate between them and tubercle bacilli. Guinea-pig inoculation should be used in case of failure to find tubercle bacilli in the ordinary way. The cystoscopic picture was not always typical. Intolerance to silver nitrate was a valuable sign. The treatment was palliative and curative; the latter was hygienic, systemic, local and operative. So much good could often be accomplished by local or operative measures that it was doubtful if these cases should be given up for the purpose of going away for good air and hygienic influences. Iodoform emulsion was soothing and often healing. Bichloride was irritating. Creosote and guaiacol in full doses were beneficial. Tuberculin was used the same as in disease of other parts of the body. In using the air cystoscope he thought he had observed some benefit from dilating the bladder with air. Removal of the diseased kidney was often followed by prompt improvement or recovery of the bladder trouble.

Dr. Guy L. Hunner of Baltimore said there were few diseases that caused so much suffering and that resisted treatment so much as bladder tuberculosis. It had been his practice to suspect tuberculosis in every case that complained of bladder symptoms, until it was proved otherwise. It was easy to rule out the common causes of cystitis. Any case of cystitis that failed to react to the ordinary methods of treatment should come under suspicion. The presence of disease of one or both kidneys was another thing that would make one suspect tuberculosis, because an ascending infection of the kidney from an ordinary cystitis was very rare. The cystoscope was very important. There was a class of cases where both kidneys were involved and where it was advisable to begin treatment at the bladder end, instead of trying to remove either of the kidneys. In some of these cases a vesico-vaginal fistula gave great comfort, especially in connection with the tub bath treatment. Two illustrative cases were mentioned. He agreed with Guyon and Casper as to the efficacy of bichloride in these cases. His experience had been that dilatation of the bladder with air broke open the ulcers, and only aggravated matters. Bichloride probably acted by setting up a cystitis which would improve the circulation. Against that was the fact that silver nitrate caused as much irritation and at the same time made these cases worse.

Dr. Willy Meyer of New York said there could be no question but what in probably more than 95 per cent. of cases tuberculosis of the bladder was a descending process, but he was firmly convinced that primary tuberculosis of the prostate, which so often followed a primary invasion of the gonococcus, did exist and was to be considered as a cause of tuberculosis of the bladder. Every means at our disposal should be exhausted in attempting to arrive at a correct diagnosis—careful history, careful examination of the twenty-four hour urine, inoculation of guinea-pigs, *x*-ray, cystoscopy, and the various tests of the functional activity of the kidney. The *x*-ray should be used before cystoscopy, in order to exclude stone. Personally, he favored the indigo-carmine test, though none of these tests was reliable alone. The finding of ulcers on the same side as the pain in the kidney was a pretty sure sign as to which side the disease was on. It stood to reason that if early diagnosis could be made, the proper treatment was to

remove the more diseased kidney as early as possible. It was not necessary to remove the ureter.

Dr. E. M. Sala of Rock Island, Ill., reported a case that he had operated on six or seven years ago, in which one kidney had been removed, followed by complete recovery from the bladder trouble. The ureter had been left in. The patient had remained well to date.

Dr. Louis E. Schmidt of Chicago reported two cases that had consulted him on account of hematuria. In each case nephrectomy was advised. The first patient, a medical student, refused operation and went under vaccine treatment. That was a year and a half ago, and he returned three or four weeks ago, with a history that two and a half months previously he had had a nephrectomy. Cystoscopy showed that his entire bladder was now tuberculous. The second patient consented and had a nephrectomy a year and a half ago, and when seen a few weeks ago was entirely free from symptoms. These cases were cited to show the value of early diagnosis and nephrectomy. In the treatment of the bladder after nephrectomy and also where the kidneys were so badly diseased that nephrectomy was not advisable, he believed that more attention should be paid to the hygienic and climatic treatment than to the local treatment.

Dr. William E. Lower of Cleveland, Ohio, said that if it was true that tuberculosis of the bladder was practically always secondary—and he believed it was—then no treatment of the bladder would be of any avail until the primary focus of the disease had been first treated. In his experience, tuberculosis of the kidney was much more frequent in women than in men, the proportion being about three to one. He had tried all manner of treatment of the tuberculous bladder following nephrectomy, but had obtained the best results with the method of Rovsing, the injection of a 5 per cent. solution of carbolic acid into the bladder, about once a week, and allowing it to remain in the bladder from twenty to thirty minutes. He had noticed that the ulcers were not around the ureteral opening, but in the back and most sacculated portion of the bladder.

Dr. Korsell of Chicago reported a case of tuberculosis of the bladder which was not accompanied by tuberculosis of the kidney. After several weeks in bed and local treatment with iodoform emulsion, together with constitutional treatment, the patient made a rapid recovery. The origin of the infection was probably a tuberculous peritonitis, the bacilli reaching the bladder through the urine. Examination of the urine every day for a week gave negative results.

Dr. Karo, in closing, said the evidence offered by Dr. Korsell was not sufficient to disprove kidney tuberculosis. In the case of tuberculosis of the kidney the diseased portion of the kidney might become walled off and the case recover without interference. In his opinion, it was absolutely useless to treat a tuberculous bladder so long as one or both kidneys were affected. A little experience would enable one to differentiate between the smegma bacillus and the tubercle bacillus. The smegma bacillus was shorter and thicker and differently grouped on the slide. Hygienic measures were good where they could be carried out, but they were not applicable in the poorer classes. Where one kidney was tuberculous and the other healthy, nephrectomy was the operative procedure of choice. If both kidneys were affected, usually one was more so than the other, and after having found out by the phloridzin test, by determining the freezing point of the blood, and by every other means at his disposal which of the affected kidneys was in the worse condition, he would not hesitate to make a nephrectomy on the more diseased side. He preferred to leave the ureter to take care of itself. He had not had good results from suturing the ureter in the wound.

Dr. Lewis, in closing, said he believed it would be a source of danger for one to rely with confidence on his ability to differentiate between the smegma and the tubercle bacillus in a given specimen. It was true that there were differences, but he would rather place his reliance on the exclusion of the smegma bacilli from the specimen than on the differences in size, shape and grouping. He believed that the ureter should be left in, thus avoiding the additional risk, and it could be removed later if this should be found necessary.

Tuberculosis of the Female Generative Organs.—Dr. I. S. Stone of Washington, D. C., read this paper. In the vast majority of cases disease of these organs was secondary, although it might be impossible to find the seat or point of entrance of the infectious process. Repeated experiments and observations had failed to establish a definite method by which tuberculosis selected any organ such as the uterine adnexa for the implantation of the morbid process. The writer had found numerous instances of mixed infection, but he did not think a previous infection invited the implantation of tuberculous disease. Proof of the direct entrance of tubercle bacilli through the vagina into the uterus and thence to the tubes and peritoneum had not been obtained. Some gynecologists were inclined to believe that many of the erosions of the cervix in virgins, attended with leucorrhœa, were due to tuberculosis. The diagnosis with tuberculin had rarely been tried. The median incision was advised, through which the peritoneum, mesentery, and perhaps other abdominal contents might be examined and treated. This was important, because with the vaginal incision tuberculosis of the intestine or peritoneum might be overlooked. The curative results of hysterectomy, salpingectomy, and oöphorectomy were nearly always satisfactory when there was but little extension of the morbid process to other organs.

Tuberculosis of the Peritoneum.—Dr. F. B. Lund of Boston read this paper. After detailing the pathology and the symptoms and physical signs, he said the chief interest to the surgeon lay in the treatment. The progress of the surgical treatment of tuberculous peritonitis from its accidental discovery, through its empirical stages, to its present scientific position, was one of the most interesting bits of present day surgical history. In 1862 Sir Spencer Wells opened a case of tuberculous peritonitis by mistake, sewed it up again, and his patient recovered and remained well. Since then the operation of opening the abdomen for this condition had been practised. König, however, first formally advised the operation in 1884. J. B. Murphy in 1904 observed and was one of the first to appreciate that in many of these cases in women the Fallopian tube was thickened and ulcerated, and that the end of the tube was open and discharging its contents into the abdominal cavity. Murphy also called attention to the fact that if the focus of supply to the peritoneum was a mesenteric gland or an appendical tuberculosis, its removal was indicated, as was the removal of a tuberculous tube. Therefore, the rational modern treatment was to discover and remove the source of infection.

Dr. Guy L. Hunner of Baltimore said it was really remarkable how certain cases of very marked tuberculous disease of the pelvic organs and peritoneum, where the patients were in extremely bad condition, would still recover after suitable operative interference. He mentioned three cases to illustrate this point.

Dr. Emil G. Beck of Chicago said that after the removal of the source of the infection the peritoneum would as a rule take care of itself, but if the tuberculosis of the peritoneum were very far advanced it would not take care of itself, and in those cases before closing the abdomen he advocated the injection into the peritoneal cavity of about two drams of bismuth paste. It was harmless.

Dr. Lund, in closing, said he thought the danger of attempting any local treatment of the peritoneum lay in the fact that one would be trying to produce adhesions, and the results of the treatment could not be localized at the point where it was desired. The greatest step in advance was made when Dr. Murphy directed attention to the primary focus of the disease.

SECTION ON TUBERCULOSIS IN CHILDREN.

Third Day—Wednesday, September 30.

Children of the Tuberculous.—Dr. THEODORE B. SACHS, of Chicago, read this paper. He said that examinations had been made of three hundred and twenty-two children of the laboring class, with surroundings favorable to the transmission of the disease. There were found to be 20 per cent. of the children under five years of age; 28 per cent. between five and ten years; 25 per cent. between ten and fifteen, and 14 per cent. between fifteen and twenty years of age. There was a high rate of mortality from non-tuberculous disease in the first year of life. The rate of mortality from tuberculosis increased with age. Twenty-nine per cent. of all children showed positive evidences of the disease; 28 per cent. of tuberculosis in children were born before the parent became tuberculous; 31 per cent. of tuberculosis in children were born after the parent became tuberculous. The difference was ascribed to the closer contact with infection in the more crowded surroundings, into which the family drifted, with an abridgment of the working capacity of the parent. With the advance in age, from infancy to adult life, there was a gradual development of stamina of the physical type, with growing frequency of the tuberculin reactions. He made a study of the range of temperature of apparently healthy children and children of the tuberculous, in the same surroundings. Phthisis of the adult in many cases was the final result of infection which occurred in childhood.

The Occurrence of Pulmonary Tuberculosis in the Children of Tuberculous Parents.—Drs. JAMES ALEX. MILLER and J. OGDEN WOODRUFF of New York presented this report, which was based upon the examination of 150 children of tuberculous parents. Of these 150 cases, 76 (51 per cent.) were found to be positively tuberculous; 43 (29 per cent.) were found to be non-tuberculous, and 31 (20 per cent.) were found to be doubtful. The main factors in arriving at a diagnosis were (1) malnutrition; (2) pulmonary symptoms and physical signs; (3) enlarged cervical nodes; (4) hypertrophied tonsils and adenoids; (5) tuberculin tests; (6) sputum examinations. Of all these the most valuable and consistent appeared to be the pulmonary symptoms and signs and the tuberculin tests. The physical signs in children under ten years of age were not those of the typical apical lesions usually found in adults, but were often signs of a persistent localized bronchitis, usually in the lower anterior chest. The ophthalmic, the cutaneous, and the hypodermic tuberculin tests were all employed, and the results of the local tests were corroborated in all cases in which the hypodermic test was also given. The cutaneous test was fully as reliable, if not more so, than the ophthalmic test. Enlarged cervical nodes and hypertrophied tonsils and adenoids did not seem to be a determining factor in the diagnosis of tuberculosis. Malnutrition was sometimes the only appreciable evidence of tuberculosis in children. The examination of the sputum was of little value. The results of his examinations and investigations lead to the conclusion that pulmonary tuberculosis was very frequent in the children of tuberculous parents.

A Clinical Study of the Transmission and Progress of Tuberculosis in Children Through Family Associations.—Drs. CLEVELAND FLOYD and HENRY I. BOWDITCH of Boston presented this paper, which consisted of a study of one thousand children that had been under observation for a number of months at the Boston Consumptive Hospital. The patients ranged in age from a few months to fifteen years, and the majority had been exposed to phthisis for a varying length of time by the presence of open cases in the home. Charts were presented which showed the following: There were under observation 475 boys and 525 girls, a total of 1,000 cases. There were 35 cases one year and under; 249 cases between the ages of one and five; 716 cases between the ages of five and fifteen, a total of 1,000 cases. With regard to the family history, there were 500 living phthisical parents; 179 parents had died of phthisis; while in 321 there was no history of phthisis obtainable, a total of 1,000 cases. Of the children of the living phthisical parents (500) and those of the parents who had died of phthisis (179) there was pulmonary consolidation in 36 per cent. In all of these 1,000 cases signs and symptoms were present in 66 per cent. With regard to the examination the tonsils were found to be affected in 493 cases; there were adenoids in 145 cases; there was a mitral stenosis in 2; there was a mitral regurgitation in 10; the apices were involved in 262; the middle and lower lobes were involved in 100.

Human Contagion as a Factor in Infantile Tuberculosis.—Dr. JULES COMBY of Paris offered this communication, in which it was stated that tuberculosis was not hereditary, and that the transmission of Koch's bacillus from the mother to the fetus by way of the placenta was exceptional, nor was the soil inherited any more than the seed. There was no doubt that tuberculous parents transmitted tuberculosis to their children, but they did so through contagion. Family contagion explained almost all cases of infantile tuberculosis. Transmission through the milk or flesh of tuberculous cows played a very insignificant part in the transmission of the disease to the human species. The infant could be fully protected against this danger by a proper selection of cows and the sterilization of the milk. Their clinical observations and investigations had shown that tuberculous children were found only in families in which there were tuberculous members, regardless of the kind of milk consumed. On the other hand, they constantly found at autopsies tuberculosis of the peribronchial glands, which therefore represented the aerial port of entry of the bacillus of Koch. Among 1,432 autopsies on children from the hospitals of Paris during the course of fourteen years, Dr. Comby found 529 tuberculous subjects, or about 37 per cent.; among 216 infants from zero to three months, four were found to be tuberculous, or less than 2 per cent.; of 1,008 infants from zero to two years, 252 were found to be tuberculous, or about 25 per cent. After the second year, the proportion of tuberculous cadavers attained 45, 50, 60 and 65 per cent. All this he believed to be fully explained by human contagion. Prophylaxis should occupy itself with the phthisical human beings and not with cows.

The Public Schools in the Prevention of Tuberculosis.—Dr. JOHN S. LANKFORD of San Antonio, Texas, presented this paper.

Obstructive Abnormalities of the Oro-Naso-Pharynx, a Powerful Predisposing Factor to Tuberculosis in School Children.—Dr. JOHN J. CRONIN of New York read this paper. He said that the high percentage of deformities of the nose, throat and pharyngeal spaces found among children from tuberculous homes indicated that whatever might be the reason of the abnormal development of embryonal lymphoid tissue, the presence of the enlarged tissues in vital cavities predisposed the child thus affected to a lessened resistance against the constant exposure to tuberculosis.

Placental Transmission of Tuberculosis.—Dr. ALDRED SCOTT WARTHIN, Professor of Pathology, University of Michigan, read this paper (with lantern slide demonstration). He called attention to the present status of congenital tuberculosis, and said that this condition was ordinarily regarded as extremely rare. He gave a brief analysis of the reported cases. The current teachings regarding "non-inheritance" of tuberculosis was responsible for the increasing laxity regarding marriage and pregnancy in the case of tuberculous women. Congenital tuberculosis was the result of placental transmission. In the pregnant tuberculous woman, even in the early stage of infection, chances favored the entrance of the bacilli into the blood-stream and thence to the placental sinuses. Here the bacilli might drop out of the circulation upon either the decidual endothelium or the chorionic syncytium. The

chorionic syncytium possessed no especial resistance to the tubercle bacillus. On the contrary, it appeared that it was easily injured by the bacilli gaining entrance to the placental sinuses. It was no more immune to the action of the tubercle bacillus than was the vascular endothelium in any part of the body. The lodgment upon the syncytium of active bacilli was followed by degeneration and necrosis of the syncytium at the point of lodgment. This was followed by the formation of an agglutination-thrombus upon the damaged syncytium. This thrombus later became organized into a tubercle, the epithelioid cells and giant-cells coming from the stroma of the villus. Secondary caseation might then occur. The tubercle bacillus might also pass through a syncytium apparently showing no damage. Tuberculosis of the placenta manifested itself in five forms: (1) Decidual; (2) intervillous; (3) intravillous; (4) intravascular chorionic; (5) chorio-amniotic. The most common forms were the decidual and intervillous lesions. In the case of the former no tubercles were ever formed, the decidual lesion consisting of a localized area of necrosis and thrombosis without the formation of epithelioid or giant-cells. The primary event in this lesion was the necrosis of the endothelium of the decidual sinus at the point of lodgment of the tubercle bacillus. In the intervillous lesions the syncytial necrosis was the primary event. The lesions of endothelium or syncytium lead to the formation of hyaline or or agglutination thrombi, which later might become transformed into epitheloid tubercles. The same process took place in the lesions arising in the chorionic vessels. Since tubercle bacilli might pass the placenta without causing local lesions the absence of the latter did not signify that the fetus had escaped infection. In the case of placental lesions the chances were infinitely greater that bacilli might gain entrance into the fetal circulation. In the fetal blood stream they might be present in great numbers without exciting local lesions. The occurrence of "local" infection of the new-born was very probable. In conclusion he said that the occurrence of pregnancy in a tuberculous woman favored the entrance of tubercle bacilli into the blood stream and then into the placental sinuses. The placenta was not a perfect filter for micro-organisms. It had no especial immunity against the tubercle bacillus. Congenital tuberculosis as the result of placental transmission was a definite factor in the etiology of tuberculosis and could not be dismissed with its mere recognition as a very rare possibility. While, of course, relatively rare, it was more common than supposed, and must be borne in mind as a definite possibility in all cases in which the question of marriage and pregnancy of tuberculous women came up for consideration.

Fourth Day—Thursday, October 1.

The Value and Reliability of Calmette's Ophthalmic Reaction to Tuberculin for the Diagnosis and Differentiation of Tuberculous Lesions from Other Diseases in Infants and Young Children.—Dr. E. Mather Sill of New York read this paper. He believed the method to be a great aid in the diagnosis of tuberculosis in children, in the early as well as the late stages. There were very few cases reported of injury to the eye or conjunctiva, and he said they should not forget the fact that this test had been used in many thousands of cases all over the world.

Experiments in the Ophthalmic Inoculation of Tuberculin.—Dr. Henry K. L. Shaw of Albany, N. Y., read this paper, which was based upon the results of two series of the tests in children under twelve months of age. He first called attention to the fact that the subcutaneous method would never become popular, because it required hospital care and good nursing. In the first series of cases there were 47 infants, 14 of them under five months of age, and he obtained no reaction from the use of the human tuberculin except in one case. In this patient he got a slight reaction; it was a case of an old empyema with a discharging sinus. In the second series there were 34 cases, 16 under three months. In this series he used bovine tuberculin and obtained no reaction. Even with a strong solution of tuberculin he obtained no irritation. There were no bad effects in either series.

Some Clinical Observations on the von Pirquet Reaction in Children.—Dr. Henry Heiman of New York said that 104 children were vaccinated according to the v. Pirquet method at the Mt. Sinai Hospital. Twenty-six children showed a positive reaction and 78 a negative one. The 26 children that gave a positive reaction suffered from tuberculous adenitis, tuberculous meningitis, tuberculous peritonitis, solitary tubercle of the brain, pulmonary tuberculosis (probable), pleurisy with effusion, bronchopneumonia, glioma of the retina and multiple dactylitis, amaurotic family idiocy, rickets, intestinal intoxication, and sarcoma of the kidney. In the cases of tuberculous meningitis, 80 per cent. gave a negative reaction, and this was probably due to the fact that the vaccination was performed during the terminal stage of the disease, when antibodies and bacteriolysins were absent.

The Comparative Value of Recent Tests for Tuberculosis.—Dr. Henry Dwight Chapin of New York read this paper, which was based upon 70 cases in which the conjunctival test was employed. The ages of those tested varied from six months to thirteen years. A uniform preparation of tuberculin was used, *i.e.*, a .5 per cent. solution in alcohol of Koch's old tuberculin. The observations were undertaken with several objects in view: (1) To determine the specificity of the test; (2) to learn if the activity or extent of the lesion bore any relation to the degree of reaction; (3) was it of value in prognosis? (4) was the conjunctival reaction free from danger? With regard to the specificity of the test, all the cases were clearly tuberculous, the majority of them being afflicted with bone diseases, others having pulmonary tuberculosis and supurating glands, tuberculous meningitis and tuberculous peritonitis. The conjunctival test was positive in all cases that were proven to be tuberculous. With regard to the degree of reaction, he called attention to the fact that in the young child crying interfered with the reaction, the tears washing the tuberculin away. Various degrees of reaction were recognized. Some cases responded quickly and were mild cases, while others responded slowly and were severe cases. Some reactions were latent, not appearing for hours or even days after the tuberculin was applied. All these things he considered to be significant. With regard to the dangers of the conjunctival reaction, it had been claimed by some that lesions of the eye that were not tuberculous were aggravated by this test. In their experience the ordinary conjunctivitis did not contraindicate the test. They had seen no injurious effects in the 125 cases in which the test was employed. The worse case they ever had was a very mild conjunctivitis which lasted a few weeks. A careful examination of the eye was always made before they employed the test. The conclusions they arrived at regarding the opsonic index were as follows: (1) The opsonic index varied with the severity of the disease; (2) the technique for obtaining the index was so difficult and varied so widely that it was of little practical value in diagnosis; (3) the index when obtained by a careful technique was of value as showing the resistance of the patients.

The von Pirquet Method as an Aid to the Diagnosis of Tuberculosis in Infancy and Childhood.—Dr. Louis Fisher of New York said the von Pirquet method had proved an aid in strengthening the suspicion of latent tuberculosis. The ocular reactions of Calmette had been attended by severe ocular complications, both in this country and abroad. No such danger had been recorded with the von Pirquet method. The reaction, if positive, would be visible in very young infants in about from five to seven days. In older children it would sometimes remain several weeks. The reaction was positive in

tuberculous meningitis, tuberculous coitis, as well as in pulmonary tuberculosis, and in tuberculous osteomyelitis.

Serum Disease and the Cutireaction.—Drs. L. Detre and N. Berend of Budapest presented this communication.

Frequency of Tuberculosis in Childhood.—Dr. Clemens von Pirquet of Vienna read this paper. He said that as the result of over 1400 examinations with the cutaneous tuberculin test at the Escherich clinic, a table had been prepared which showed the increase of infection with tuberculosis from year to year. These results had been compared with the statistics made with the post-mortems of children. He discussed the significance of the different kinds of reactions which appeared in early and later childhood. Dr. von Pirquet proposed international statistics to be prepared in the following manner: That children of all ages, for instance, kindergarten and school children, be tried with the cutaneous test on the first day; on the following day all should be inspected. Those who showed a reaction should be noted as belonging to the class of "early reactions," which practically meant having had the infection in the latter years. A week later those children who showed no reaction on the first trial should be again tried. A great percentage of older children would now react, and they belonged to the class of "secondary reaction," which generally meant having had the infection in previous years. Those children who had not reacted on the above occasions belonged to the third class, which could be considered as those practically free of tuberculosis. In order to have a certainty regarding the third class, one could inject the non-reacting children on the following day with 1. mg. of tuberculin, according to the proposal of F. Hamburger, and inspect those children the next day as to the local subcutaneous reaction. This trial, of course, would only be possible in hospitals, whereas in schools one must be contented with the cutaneous trials, which which could be made without any inconvenience to the children. In this way one could take note in the different towns of the percentages of infection and the ages at which such infections occurred, and consequently could form conclusions as to hygiene.

An Expeditious Method for the Detection of Tuberculosis Among School Children.—Dr. Harland Shoemaker of Philadelphia, advocated the use of the torsion balance at stated intervals, by means of which one could determine the loss of weight in any child, a method which was easy of application and which was of greater clinical importance than the physical signs. The use of this instrument would indicate those who were healthy and those who were sick. It was applicable to large bodies of individuals, whether in schools, in shops, stores or elsewhere. He called attention to the fact that there was estimated to have been in the public schools in Philadelphia in 1906, 159,217 children: of this number only eight were reported as being evidently tuberculous. The vital statistics for the same year showed the deaths under one year, 118; between the ages of one and two years, 76; between two and five years, 94; between five and ten years, 65; between ten and fifteen years, 65; between fifteen and twenty years, 337. There were 355 boys and 400 girls. The estimated population of Philadelphia was 1,500,395.

The Diagnostic Value of Lumbar Puncture in Acute Tuberculous Meningitis in Children.—Dr. Frederic E. Sondern of New York said that the bacteriological examination of the cerebrospinal fluid rendered the best service in diagnosis though the cytology was also important, particularly in the absence of microorganisms. The practical information obtained from the pressure, appearance, density, amount of albumin and other chemical data, the amount of sediment, the tendency to coagulation, the toxicity, the freezing point, and the transmission of some administered drugs to the cerebrospinal fluid, was often of decided value, but always secondary to the above. The examination should be as complete as circumstances and the available amount of the specimen permitted. The chief diagnostic and differential features were: In tuberculous meningitis the pressure of the cerebrospinal fluid was increased; the appearance was usually transparent and colorless, occasionally slightly opalescent; the density was not much increased; the albumin between ¾ and 2 per mille by weight; the coagulum was slight and frail; the sediment was slight; cytology, average number of lymphocytes, 86 per cent.; bacteriology, tubercle bacilli present in 88 per cent. of the cases. If tubercle bacilli were present, a relative polynuclear increase might indicate mixed infection. In the absence of bacilli, if lymphocytes predominated, the search should be repeated, and a possible meningism of typhoid, pneumonia, etc., should be kept in mind. Purulent specimens usually offered no difficulty in the diagnosis. The relative polynuclear cell increased and almost invariable presence of intracellular diplococci distinguished cases of cerebrospinal meningitis.

Overcoming the Predisposition to Tuberculosis and the Dangers from Infection During Childhood.—Dr. S. Adolphus Knopf of New York said that the object of his paper was to call attention to the methods which might be employed to overcome predispositions to tuberculosis and to prevent children from becoming infected. How could the predisposition be overcome? One should begin with the child *in utero*. The mother-to-be should have the best of hygienic surroundings, the best of food, and should live in a well-ventilated room. After birth the child should be taken into the open air: it should be gradually taken there and become accustomed to breathing fresh and pure air. The fear of night air was a nightmare. There was no such thing as catching cold from fresh, cold, pure air. As the child grew up it should be taught how to breathe and have a chance to breathe. If there were any obstructions to breathing they should be removed. It was a very important matter that the child should be taught to breathe properly.

First Aid in Better Lung Development for Children and Olfactory Nerve Influence on Respiration.—Mrs. Emily Noble of New York said that the lungs had a plentiful supply of nerves, originating in both the cranial and sympathetic systems, and some of them controlled respiration which in the human being had a double function, the interchange of gases between the blood and the inspired air and also, when respiration was normal, the rhythmic vibration of all the organs of the body. All muscles controlling the respiratory tract were designed for use. Muscular activity could only find volition through expenditure of nervous energy, from some nervous center. The olfactory bulb was an important nerve center. Although the action, chemical and physiological, of many functions of the different nerve centers was somewhat obscured, the action of the olfactory nerve influenced in controlling and aiding the respiratory muscles could not be disproved, although very few physiologists of the Western Hemisphere were familiar with the nervous mechanism that controlled respiration. One of the best aids for the prevention of tuberculosis was the spread of knowledge. People must be taught how to take hand in "first aid," and be educated in the simple laws of health. It was in the interest of millions of defective breathing children in homes and public schools that they respectfully submitted an outline of their crusade work. The object of this crusade was to establish centers in all large cities, where parents and teachers might obtain free scientific instruction and practical suggestions for the prevention of nasal and pulmonary troubles in children. The crusade was self supporting.

The Value of Children's Gardens in Congested Districts.—Mrs. Henry Parsons of New York told of the values of (1) an attractive open-air space near the home; (2) gentle activities; (3) watching of living green things

and insect life in keeping the little sufferers' minds off their pain; (4) a beautiful picture left in the mind to be thought of in the dismal hours of pain at home. Such gardens located throughout the city would accommodate thousands of such children for six to eight months in the year, year after year, in comparison with the few that could be sent to the seashore, mountain, or sanatoria for short stays. The possibility of teaching hygiene, within the children's comprehension, by simple experiments with plants in their own plots which would lead them to see why fresh air, cleanliness, and sunshine were absolutely necessary to life and vigor and which would lead them to demand such surroundings in their own homes.

The Hygienic and Climatic Prophylaxis of Tuberculosis in Childhood.—Dr. Frederick L. Wachenheim of New York believed that good general nutrition was one of the best safeguards against tuberculosis in children, and to secure this one often had to combat disturbances of digestion or neurotic anorexia. To stimulate the appetite and digestion nothing was so useful as exercise, preferably out of doors. Over-exercise, however, was harmful, and might even predispose to tuberculosis. In the achievement of hardening one was practically limited to the application of cold; cold fresh air ranked first among their hardening measures, and cold bathing second; both were to be employed guardedly, especially in infancy, with gradually increasing strenuousness as the child grew older, excess in this direction also being harmful. Cold bathing should not be attempted in infancy; in later childhood sea-bathing was of special tonic value.

(To Be Continued.)

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Diseases of Infancy and Childhood; Their Dietetic, Hygienic, and Medical Treatment. By Louis Fischer, M.D. 8vo, 980 pages, illustrated; cloth. F. A. Davis Company, Philadelphia.

Semi-Annual Report of Schimmel & Co. 12mo, 196 pages; paper. Fritsche Brothers, New York.

Compendium der Verbandlehre. By Dr. Eduard Sonnenburg and Dr. Richard Muhsam. 8vo, 96 pages, illustrated; cloth; 3 marks. August Hirschwald, Berlin.

Pain. By Dr. Rudolph Schmidt. 8vo, 326 pages, illustrated; cloth. J. B. Lippincott Co., Philadelphia.

Essentials of Dietetics in Health and Disease. By Amy Elizabeth Pope and Mary L. Carpenter. 12mo, 249 pages, illustrated; cloth. G. P. Putnam's Sons, New York.

Points of Practice in Maladies of the Heart. By James Sawyer, Knt., M.D. (Lond.), F.R.C.P., F.R.S. (Ed.), F.S.A. 12mo, 96 pages; cloth. Cornish Brothers, Ltd., Birmingham.

Pharmaceutical Preparations. By A. Emil Hiss, Ph.G., and Albert E. Ebert, Ph.M., Ph.D. 8vo, 576 pages; cloth; $3.00. G. P. Engelhard & Company, Chicago.

Pulmonary Tuberculosis. By Sherman G. Bonney, A.M., M.D. 8vo, 778 pages, illustrated; cloth; $7.00 net; half morocco, $8.50 net. W. B. Saunders Company, Philadelphia.

Transactions of the American Society of Sanitary and Moral Prophylaxis. Vol. 2, 8vo, 246 pages; paper.

The Air and Ventilation of Subways. By George A. Soper, Ph.D. 8vo, 244 pages, illustrated; cloth; $2.50 net. John Wiley & Sons, New York.

Die Verletzung der Arteria Meningea Media. Von Dr. Custodis. 8vo, 200 pages, illustrated; cloth; 3 marks. August Hirschwald, Berlin.

Yearbook of the Department of Agriculture (1907). 8vo, 798 pages, illustrated; cloth. Government Printing Office, Washington.

Cancer. By P. Menetrier. 8vo, 662 pages, illustrated, paper; 12 francs. J. B. Bailliere et Fils, Paris.

Manual of Midwifery. By Thomas Watts Eden, M.D., C.M. (Edin.), F.R.C.P. (Lond.), F.R.C.S. Ed. 8vo, 556 pages, illustrated; cloth; $3.50 net. W. T. Keener & Co., Chicago.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

New Jersey State Board of Medical Examiners.

June 8, 1908.

(Answer ten questions, but no more, in each of the papers.)

ANATOMY.

1. Give a general description of the vertebral column.
2. Differentiate between thoracic and lumbar vertebræ.
3. Describe the hyoid bone. Name muscles attached to it.
4. Locate and describe the maxillary sinus (antrum).
5. Give origin, branches, and parts supplied by the inferior maxillary nerve.
6. Ulnar artery: Give origin, branches, and parts supplied by it.
7. Describe the spinal cord.
8. Locate and describe the inguinal or spermatic canal; state its boundaries and contents.
9. Give location, shape, size, weight, and structural formation of the pancreas.
10. Outline by word or drawing the location of the kidney.
11. Name the arteries supplying the uterus and give their origin.
12. Radius; name articulations. What muscles are attached to the radius?
13. Give origin, insertion, nerve and blood supply, and action of any one of the following muscles: pectoralis major, gluteus medius, pronator radii teres.
14. What artery supplies the dura mater?
15. In fracture of the surgical neck of the humerus, which muscles (*a*) elevate upper fragment under the coraco-acromial ligament, (*b*) draw the lower fragment inward, and (*c*) throw the humerus obliquely outward from the side?

PHYSIOLOGY.

1. Define physiology.
2. Describe a typical nerve cell.
3. What is reflex action; a superficial reflex; a deep reflex? Give one example of each.
4. What nerves control the heart? What does each do?
5. What nerves control the gastro-intestinal physiology?
6. What is metabolism?
7. What is urea, and where is it developed?
8. Give daily amount, reaction, and specific gravity of urine.
9. Name in order of importance the organs in which heat is developed, and those by which it is thrown off.
10. Give normal range of temperature in childhood and adult life.
11. Name four factors that directly affect the pulse, and give the normal pulse rate.
12. Name four factors that affect weight.
13. What is coordination, and upon what does it depend?
14. Describe the action of accommodation, and state why it fails in old age.
15. What are the four chief functions of the nasal cavity, and what disturbances follow its obstruction?

CHEMISTRY.

1. What is the general nature of urinary sediments, and how are they recognized?
2. Describe a process by which arsenic may be detected in organic matter.
3. State the general qualities of bile and mention its chief constituents.
4. State the general chemical properties of alkaloids.
5. On what chemical hypothesis are lithium compounds administered to gouty patients?
6. What is ozone, and how does it differ from common oxygen? Under what circumstances is ozone found?
7. Give composition, properties, mode of manufacture of, and tests for carbolic acid.
8. Give the average composition of human urine and state by what conditions the composition is influenced.
9. Illustrate by formulæ the difference between ferrous and ferric salts.
10. State the best temporary antidote to poisoning by mercury.
11. Enumerate the metals, salts of which are frequently employed in pharmacy.
12. State the laws of constant and reciprocal proportions.
13. Explain the meaning of terms "reaction" and "reagent."
14. Give Marsh's test.

15. What is the general chemical character of volatile oils?

MATERIA MEDICA AND THERAPEUTICS.

1. Name the paths by which medicines enter the circulation.
2. State (*a*) principle, (*b*) taste, (*c*) medical uses, and (*d*) adult dose of podophyllin.
3. (*a*) Define cardiac depressants; give (*b*) three examples; (*c*) adult dose, and (*d*) specific indications for use.
4. (*a*) Describe at least two movements of massage, (*b*) their application in practice, and (*c*) benefits to be derived.
5. Mention (*a*) three diuretics, (*b*) therapeutic employment, and (*c*) adult dose of each.
6. Specify (*a*) three official preparations of digitalis, (*b*) their physiological action, and (*c*) maximum dose of each.
7. Enumerate therapeutic use, dose, and effect of (*a*) acetanilid, (*b*) heroin, (*c*) terebene.
8. Give (*a*) Source of opium, (*b*) its effect on the nervous system, circulation, respiration, and pupils.
9. Differentiate the effects on the arterial system of (*a*) strychnine, (*b*) nitroglycerin, and (*c*) aconite.
10. (*a*) Explain action of emmenagogues. (*b*) Give two examples and dose of each.
11. (*a*) What class of acids are employed to acidify alkaline urine? (*b*) Specify and give adult dose of each.
12. (*a*) Outline a dietary for interstitial nephritis, and (*b*) diabetes mellitus.
13. (*a*) Prescribe in proper form for acute diarrhea in a child 4 years of age, and (*b*) explain action of each ingredient.
14. Write (*a*) indications and (*b*) the contraindications for KBr; give adult dose.
15. Normal NaCl solution (*a*) preparation, (*b*) methods of administration, (*c*) effects.

HISTOLOGY, BACTERIOLOGY, PATHOLOGY.

(Answer only ten questions; not less than three on each branch.)

Pathology.

1. What is the difference between hypertrophy and enlargement?
2. What are the modes of spread of pyogenetic microorganisms? Describe each mode.
3. Describe the repair of a simple fracture of bone.
4. What pathological conditions are productive of icterus?
5. Describe the macroscopic and microscopic appearance of carcinoma of the breast.

Histology.

6. How many kinds of marrow are there? Name them. Where does each occur? How do they differ?
7. Describe non-striated muscular tissue and name its principal localities.
8. Describe the gross arrangement of the suprarenal capsule. Name and describe the three layers of the cortical portion.
9. Describe the structure of the tympanic cavity and the mastoid cells.
10. Describe the general structure of the air passages.

Bacteriology.

11. Why does the air in summer contain more bacteria than in winter?
12. Define disinfectant, germicide, antiseptic, and deodorizer.
13. Differentiate between ptomains and leucomains.
14. Differentiate between toxemia and septicemia.
15. Why is the chemical disinfection of tuberculous sputum difficult, and what is the best disinfectant for general use?

PRACTICE OF MEDICINE.

1. Describe (*a*) lavage, (*b*) gavage.
2. Give causes of nasal hemorrhage.
3. Differentiate pallor, anemia, chlorosis.
4. Differentiate vesicular and bronchial breathing.
5. Differentiate renal, hepatic, and intestinal colic.
6. Give four physical signs of consolidation of lung tissue.
7. Describe (1) dry, (2) moist râles, and give significance of each.
8. Describe artificial feeding of an infant, month by month during the first year.
9. Describe eruption of (1) measles, (2) scarlatina, (3) varicella, (4) and variola.
10. Describe the *x*-ray. What are its uses, its dangers, and how can latter be avoided?
11. Where and what is the cause of a systolic murmur heard at the ensiform cartilage.
12. What is hemiplegia, paraplegia, paralysis agitans, and tabes dorsalis? Describe the walk in each.
13. What are the four physical signs of a cavity of the lung communicating with the bronchial tube?
14. Describe the various steps in making a complete uranalysis, giving your reasons and what you expect to find in each.
15. Locate on the surface of the thorax the points at which the four principal valve murmurs are heard with greatest intensity.

SURGERY.

1. Discuss rotary lateral spinal curvature.
2. Diagnosis and treatment of rupture of the urinary bladder.
3. What are the indications for trephining in fractures of the skull?
4. Mention the causes of ulceration of the cornea.
5. Describe in detail how you would proceed in retention of urine due to stricture of the urethra.
6. Give the causes of necrosis of bone. Define (*a*) sequestrum, (*b*) involucrum.
7. Describe the different varieties of hemorrhoids.
8. What pathological conditions may cause enlargement of the knee.
9. Indication for intravenous injection of normal saline solution. Technique.
10. Etiology, diagnosis, and treatment of retropharyngeal abscess.
11. Diagnosis and treatment of fracture of the neck of the femur.
12. What is the most common dislocation of the shoulder joint? Describe reduction by manipulation.
13. Aneurysm: Causes, diagnosis, and treatment.
14. Give the general characteristics of sarcomata.
15. What is surgical shock? Treatment?

OBSTETRICS AND GYNECOLOGY.

1. Name the processes of fecundation.
2. What changes does the uterus pass through after fecundation?
3. In threatening perineal laceration, what operative or other measures should be employed to prevent a tear?
4. Describe the first stage of labor.
5. Describe your method of conducting labor through the second stage, in (*a*) L. O. A.; (*b*), shoulder presenting.
6. What conditions justify the induction of abortion?
7. What should precede any abortion and how may the operation be safely performed when necessary?
8. (*a*) What conditions favor post-partum hemorrhage? (*b*) What precautions should be taken to avoid it? (*c*) Describe methods of controlling it.
9. Describe method of management of case of eclampsia beginning during first stage of labor.
10. Name symptoms, method of diagnosis and proper treatment of rupture of the uterus complicating labor.
11. Mention the manifestations of syphilis which may appear on, in, or around the female genitals.
12. How may retrodisplacements of the uterus be treated either by mechanical or surgical measures?
13. Give the symptoms, diagnosis and treatment of urethral caruncle.
14. Within the limit of 100 words describe vaginal tampons and their uses.
15. Outline treatment for dysmenorrhea.

HYGIENE AND MEDICAL JURISPRUDENCE.

1. In selecting a house-site what is to be avoided and what sought?
2. (*a*) Why would you recommend an asphalt floor in a cellar? (*b*) How deep should drains be below the floor? (*c*) How else can soil be dried?
3. What do you mean by breaking the seal of a trap? What causes it?
4. Define soil pipe and house drain.
5. Outline construction of school-house, of floors, doors, and windows; approved size of rooms, and direction of light.
6. At what age would you place a child in school, and how long should he be kept at his studies?
7. Enumerate some occupations prejudicial to health.
8. Mention the usual and best methods of physical training.
9. Describe the different forms of baths, and give rules of bathing.
10. Give methods of restoring the apparently drowned.
11. What are the usual materials from which clothing is made?
12. What are ptomains and in what are they found? Name those that have been separated. Give symptoms and treatment of ptomain poisoning.
13. Define insanity.

14. Differentiate apoplexy, opium narcosis, uremia, alcoholic intoxication, epilepsy, to the satisfaction of a court.

15. What is malpractice?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

NEW JERSEY STATE BOARD OF MEDICAL EXAMINERS.

June, 1908.

ANATOMY.

2. *The thoracic vertebræ* have a heart-shaped body with a facet or demi-facet on each side for articulation with a rib; the laminæ are broad and deep; the spinous process is long and points downward; the transverse processes are long and articulate with the tubercle of a rib; the superior articular process is directed backward and slightly outward; the inferior articular process is directed forward and slightly inward; the spinal foramen is smaller and circular.

The lumbar vertebræ have a large body, wider transversely, and with no facet or demi-facet; the laminæ are short and thick; the spinous process is horizontal; the transverse processes are "rudimentary"; the superior articular process is directed inward and slightly backward; the inferior articular process is directed outward and slightly forward; the spinal foramen is larger, and triangular.

8. *The inguinal or spermatic canal* is an oblique canal situated a little above and running parallel with Poupart's ligament. It is from an inch and a half to two inches in length, runs downward and inward, and extends from the internal abdominal ring to the external abdominal ring.

Its *boundaries* are: *In front:* the skin, superficial fascia, aponeurosis of the external oblique, and (for its outer third) the internal oblique. *Behind:* the conjoined tendon, the triangular fascia, the transversalis fascia, subperitoneal fat, and peritoneum. *Above:* the fibers of the internal oblique and transversalis. *Below:* Poupart's ligament and the transversalis fascia.

Contents: the spermatic cord in the male; and the round ligament in the female.

11. The *arteries supplying the uterus* are: the uterine artery (from the internal iliac) and the ovarian artery (from the aorta).

14. The *dura mater* is supplied by the anterior meningeal, middle meningeal, and posterior meningeal arteries.

15. In fracture of the surgical neck of the humerus, (*a*) the upper fragment is elevated by the supraspinatus, infraspinatus, and teres minor; (*b*) the lower fragment is drawn inward by the pectoralis major, latissimus dorsi, and teres major; (*c*) and the humerus is thrown obliquely outward by the deltoid.

PHYSIOLOGY.

1. *Physiology* is that branch of science which treats of the functions of living tissues and organisms in a state of health.

2. A *nerve cell* is a protoplasmic mass, with a diameter a little larger than that of a white blood corpuscle, roughly spheroidal or pyramidal in shape; and giving off several dendrites, and usually one axis-cylinder or nuraxon. The whole is called a neuron.

3. *Reflex actions* are involuntary or unconscious movements, due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve.

Superficial reflexes are such as can be elicited by stimulating the skin. *Example:* The cremasteric reflex.

Deep reflexes are such as are elicited by stimulating tendons or muscles. *Example:* The patellar reflex.

4. The *nerves which control the heart*, are: (1) The pneumogastric nerve, which slows or inhibits the heartbeats; (2) the sympathetic nerves, which accelerate or augment the beats; and (3) the intrinsic cardiac ganglia, which enable the heart to continue beating for some time after it is removed from the body.

5. The *nerves which control the gastrointestinal physiology*, are: The pneumogastric, dorsal, lumbar, and sacral nerves; also the plexuses of Auerbach and Meissner; and the sympathetic system (chiefly the splanchnics, hypogastric plexus and mesenteric ganglia).

6. *Metabolism* is a name given to the entire series of changes that occur in a cell or organism during the processes of nutrition. It is of two kinds: (1) Assimilative, or constructive, called *anabolism*, and (2) destructive, called *catabolism*.

7. Urea is the product of the nitrogenous waste of the body; it comes from the proteids of the food and tissues. It is chiefly formed in the liver.

8. The *daily amount* of urine normally voided by a healthy adult, is about 50 ounces; the *reaction* is acid; and the *specific gravity* is from about 1015 to about 1025.

9. *Heat is developed in the body*, by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the brain; (4) the heart, and (5) the thermogenetic centers in the brain, pons, medulla, and spinal cord. (It also is produced by the food and drink ingested.)

Heat is *lost* to the body by (1) the skin, through evaporation, radiation, and conduction; (2) the lungs; and (3) the excretions (feces and urine).

10. Normal range of body temperature in adults is between 98 degrees and 99 degrees F. In childhood it may vary between 97 degrees and 100 degrees F. without the appearance of anything abnormal.

11. Four factors that directly affect the pulse are: (1) The ventricular systole; (2) the elasticity of the arterial walls; (3) the volume of the blood in the vessels; (4) the peripheral resistance. The normal adult pulse rate is about seventy-two per minute.

12. *Four factors that affect weight:* (1) age; (2) sex; (3) nourishment; and (4) disease.

14. *Action of Accommodation.*—"The lens is an elastic structure, and when released from the flattening influence of its suspensory ligament tends to assume a spherical shape. During accommodation the ciliary muscle (especially the circular fibers) contracts, drawing forward the chorioid and relaxing the suspensory ligament; this diminishes the tension of the lens capsule and allows the inherent elasticity of the lens to increase its convexity. The change in curvature affects chiefly the anterior surface of the lens. This is Helmholtz's theory and the one usually accepted. Lately Tscherning has advanced a different theory; he maintains that the ciliary muscle increases the tension of the suspensory ligament during contraction, and that this causes peripheral flattening of the lens with bulging anteriorly at its center. The act of accommodation is accompanied by contraction of the pupil, and (in binocular vision) by convergence of the visual lines."—(May's *Diseases of the Eye.*)

Accommodation fails in old age, because at that time the lens has lost its elasticity.

15. The *four chief functions of the nasal cavity*, are: (1) Respiratory; (2) olfactory; (3) vocal; and (4) auditory.

The *disturbances which may follow nasal obstruction*, are: Diminution or absence of the sense of smell; redness of the nose; mouth-breathing; dyspnea; vocal impairment or nasal twang; greater tendency to nasal, laryngeal, pharyngeal, bronchial, and pulmonary diseases.

CHEMISTRY.

2. Arsenic may be detected in organic matter by the Reinisch test, which is conducted as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put it into a clean, dry glass tube, open at both ends, and apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

3. Bile is a viscid fluid, with a faint aromatic odor and an exceedingly bitter taste. It has a specific gravity of about 1020 to 1030, is alkaline in reaction, and is of a yellow or brownish color.

Its chief constituents are: Water, sodium glycocholate, sodium taurocholate, lecithin, cholesterin, fat, mucin, pigments, urea, and inorganic salts (chlorides and phosphates of sodium, potassium calcium, magnesium; and sodium carbonate).

4. *General properties of alkaloids:* Alkaloids are of two kinds, volatile and fixed. The volatile alkaloids are liquid, readily volatile without decomposition, and consist of C, H, and N. The fixed alkaloids are for the most part solid and crystalline, not, or only partially volatile without decomposition, and consist of C, H, N, and O.

Most of the alkaloids are alkaline in reaction, of a bitter taste, and of white color.

Most of the alkaloids are nearly insoluble in water, but are soluble in alcohol, chloroform, ether, and benzine; their salts are generally soluble in water and alcohol, but insoluble in the other solvents just named. They combine with acids to form salts in the same way that ammonia does.

5. Lithium compounds are administered to gouty patients on the hypothesis that the lithium salts of uric acid

are more soluble than other urates; therefore there is less chance of the formation of deposits, and if such deposits already exist their solution or removal may be aided by the lithium urate.

6. Ozone is an allotropic modification of oxygen, the oxygen being in a peculiar condition of condensation. The molecule of ozone contains three atoms, while that of oxygen contains two; three molecules of the latter are therefore condensed to two of ozone: $3O_2 = 2O_3$. Ozone is a liquid of a bluish color, peculiar odor, and is only sparingly soluble in water. Ozone is produced by the decomposition of water by the battery; by the slow oxidation of phosphorus in damp air; and by the action of concentrated sulphuric acid on barium dioxide:

$$3BaO_2 + 3H_2SO_4 = 3BaSO_4 + 3H_2O + O_3$$

7. *Carbolic acid* is phenylhydroxide: C_6H_5OH. It is a colorless crystalline substance when pure, but it soon assumes a pink color; it has a peculiar odor, and a burning taste. It is soluble in water, alcohol, and ether. It is an antiseptic, a poison, and a corrosive. It is also used in the manufacture of its derivatives which are used in medicine, and as dyes. It is made by heating phenyl iodide and potassium hydroxide at a high temperature: $C_6H_5I + KHO = KI + C_6H_5OH$.

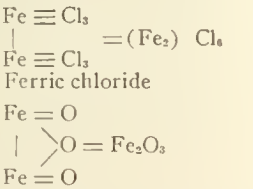
Tests: (1) With a solution of ferrous sulphate, a lilac color is produced; (2) its peculiar odor.

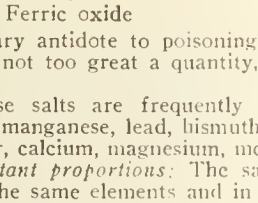
8. The following table (from Dunglison's *Medical Dictionary*) gives the average composition of normal urine:

	(Parts in 1000.)		Voided Per Day. *Grams.*	*Grams.*
Water	950.00			
Urea	28.00		520.80	35.00
Uric acid	0.60	Organic	11.16	0.75
Hippuric acid	0.35	matter,	6.51	0.44
Creatinin	0.65	37.60	12.09	0.81
Extractives	8.00		148.80	10.00
Sodium chloride	8.00		148.80	10.00
Phosphoric acid	2.00		37.20	2.50
Sulphuric acid	1.25	Inorganic	23.45	1.56
Lime (CaO)	0.25	matter,	4.65	0.31
Magnesia (MgO)	0.30	12.40	5.58	0.37
Potash (K_2O) and soda, (Na_2O)	0.60		11.16	0.75
Total	1000.00		930.20	62.49

The composition is influenced by: diet, quality of fluid ingested, exercise, and disease.

9. In *ferrous* salts, the atom of iron is bivalent. In *ferric* salts, the atom of iron is quadrivalent, and two such atoms are connected producing a double atom with a valence of six.





10. The best temporary antidote to poisoning by mercury is white of egg in not too great a quantity, and followed by an emetic.

11. The metals whose salts are frequently employed in pharmacy, are: Iron, manganese, lead, bismuth, lithium, sodium, potassium, silver, calcium, magnesium, mercury.

12. *The law of constant proportions:* The same compound always contains the same elements and in the same proportions.

The law of reciprocal proportions: The ponderable quantities in which substances unite with the same substance express the relation (or a simple multiple of it) in which they unite with each other.

13. *Reaction* has two meanings: (1) the interaction of two or more substances causing a chemical decomposition; (2) the action of substances upon certain organic pigments such as litmus.

Reagent is a substance used to bring about a reaction (first meaning above).

14. *Marsh's test for Arsenic:* This test depends on the fact that arsenic hydride is formed when nascent hydrogen acts on a compound of arsenic.

$$H_3AsO_3 + 3H_2 = AsH_3 + 3H_2O.$$

A small flask fitted with thistle funnel and a delivery tube, as for the production of hydrogen, is used; pure zinc and hydrochloric acid are introduced, and after a short time the hydrogen is ignited. It is advisable to cover the flask with a cloth before igniting the gas, as an explosion may happen unless the air has all been driven out. If the materials are pure the hydrogen flame gives no deposit upon a piece of cold porcelain brought into it, but commercial zinc usually contains arsenic. When the purity of the gas is proved, a little solution of arsenic may be poured down the thistle funnel, which will produce a more rapid evolution of gas, and the flame will become larger and perceptibly colored. A piece of cold porcelain depressed upon the flame will be covered with a deposit of metallic arsenic. The films of arsenic are metallic looking in the thicker places, brownish near the edges; they are easily volatilized by heat, and dissolve in solution of bleaching powder. A portion of the glass tube from which the gas is burnt should be heated to redness; the gas decomposes, and a deposit of arsenic appears on the tube, which may be identified in a similar way, or may be converted into crystals of oxide by cautious sublimation in an open tube.—(Fisher's *Elementary Chemistry.*)

15. Chemically, most of the volatile oils are terpenes, with the general empirical composition of $C_{10}H_{16}$ or some isomere thereof; some also contain oxygen sulphur or nitrogen. Their constitution is not settled. They are optically active, and mainly consist of two principles, stearoptene and eleoptene.

MATERIA MEDICA AND THERAPEUTICS.

1. Medicines may enter the circulation after being administered: (1) By the mouth; (2) by the skin; (3) by the rectum; (4) by inhalation; (5) by the vagina; (6) by intravenous injection.

2. Podophyllin. (*a*) *Principle:* Podophyllotoxin and Picropodophyllin. (*b*) *Taste:* Acrid, and slightly bitter. (*c*) *Medical uses:* as a purgative, a cholagogue; for chronic diarrheas, and some cases of vomiting. (*d*) *Adult dose:* Resina podophylli, gr. 1/10 to ½.

PRACTICE OF MEDICINE.

2. *Causes of nasal hemorrhage:* Injury, hemophilia, pernicious anemia, leukemia, scurvy, purpura hæmorrhagica, cerebral congestion, hypertrophy, and valvular lesions of the heart.

3. *Pallor* is merely a symptom, and may be found in several conditions.

Anemia is a disease in which the blood as a whole is diminished, or in which the number of red corpuscles is diminished. It is classified as Primary and Secondary.

Chlorosis is a disease in which the amount of hemoglobin is diminished.

5. *In renal colic:* The pain is in the region of the affected kidney, it radiates down the thigh; there are intense rigors; retraction of the testicle may be present; also history of previous attacks or of calculi; the urine may be scanty, suppressed, or bloody.

In hepatic colic: The pain is in the region of the liver, it radiates to the right scapula and toward the umbilicus; chills and sweats are common; also vomiting, and sometimes symptoms of collapse and jaundice; calculi are found, if at all, in the feces.

In intestinal colic: The pain is generally around the umbilicus; the abdomen is tympanitic; there are no rigors; there may be a history of indiscretion in diet.

6. *Four physical signs of consolidation of lung tissue:* (1) Increased vocal fremitus; (2) dullness on percussion; (3) bronchial respiration with prolonged expiration; and (4) increased vocal resonance.

9. (1) *Measles:* Eruption appears on fourth day as small dark red papules with crescentic borders, beginning on face and rapidly spreading over entire body; desquamation is branny.

(2) *Scarlatina:* Eruption appears at end of twenty-four hours, as a scarlet punctate rash, beginning on neck and chest, then covering face and body; desquamation is scaly or in flakes.

(3) *Varicella:* The eruption usually appears first on the trunk, is evident on the first day, comes in successive crops, is not shotty, and disappears on stretching the skin; the spots are unilocular, and collapse on being punctured.

(4) *Variola:* The eruption usually appears first on the forehead and wrists, and on the third or fourth day; it is first macular, then papular, then vesicular, and finally pustular; it does not appear in successive crops; the spots are multilocular, and do not collapse on being punctured; the papule is hard and shotty, and does not disappear on stretching the skin.

12. *Hemiplegia* is a condition in which one side of the body is paralyzed.

Paraplegia is a condition in which the two lower limbs are paralyzed.

Paralysis agitans is a chronic disease characterized by a peculiar walk, tremor, muscular rigidity, and sensations of heat and pain.

Tabes dorsalis is a chronic disease in which the posterior columns of the spinal cord are involved, and characterized by incoordination, pain, visceral crises, anesthesia.

THE WALK: In *hemiplegia* the paralyzed leg is swung outward and forward (by a tilting of the pelvis), and the toes scrape along the ground.

In *paraplegia* the legs and knees are in contact, and the legs and feet cross each other at each step.

In *paralysis agitans* the steps are short, quick and shuffling; the patient finds it hard to begin walking, but when once started he has to run, and finds it hard to stop.

In *tabes dorsalis* the leg is hurled forward, the foot raised needlessly high, and brought to the ground forcibly, and generally on the heel; the patient keeps his eyes on the ground and on his feet; the legs are kept somewhat apart.

OBSTETRICS AND GYNECOLOGY.

6. *Conditions which justify the induction of abortion:* (1) Certain pelvic deformities; (2) where in previous labors the head of the child has been prematurely ossified, or unusually large; (3) placenta prævia; (4) toxemia of pregnancy; (5) habitual death of the fetus toward the end of pregnancy; (6) hydatidiform mole; (7) pernicious anemia.

9. The management of eclampsia in the first stage of labor includes: (1) Controlling the convulsions (by chloroform, veratrum, or chloral); (2) emptying the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible.

13. *Urethral caruncle* is a small red fleshy growth generally situated on the posterior part of the meatus of the urethra. There are local pain and tenderness, which may be excessive; a burning sensation is experienced on urination; it may bleed. The proper treatment is to excise it or destroy it with the thermocautery.

HYGIENE AND MEDICAL JURISPRUDENCE.

3. To *break the seal of a trap* means to destroy its efficiency, whereby the sewer gases gain entrance into the house.

The *causes* are: Evaporation of the water, siphonage, the water passing too seldom along the pipe, too small a pipe, leakage or other defect in the laying of the pipes and trap.

4. *Soil pipe* is a pipe which receives the sewage from water closets, bathtubs, etc., and which carries the same to the *house drain,* which conducts it to the sewer.

7. *Some occupations prejudicial to health:* Coal miners; cutlery workers; needle makers; workers in steel or iron; stonecutters; masons, bricklayers; pottery and china workers; cotton, silk, and wool workers; furriers; workers in tobacco and snuff factories; street cleaners; carpet beaters; workers handling arsenic, mercury, phosphorus, lead, and copper, etc.

11. The usual materials from which clothing is made, are: Wool, silk, cotton, linen, leather, fur, flax.

12. *Ptomains* are basic compounds containing nitrogen, and produced from proteid material by the bacteria which cause putrefaction. They are *found* in decaying animal tissues and fluids.

The *chief poisonous ptomains* are: Tyrotoxicon, mytilotoxin, cholin, neurin, neuridin, putrescin, cadaverin, gadinin, muscarin, tetanin, typhotoxin.

The *general symptoms of ptomain poisoning* are: Onset in less than twenty-four hours after the ingestion of the noxious "food," chilliness, vertigo, headache, thirst, abdominal pains, nausea, vomiting, diarrhea, cyanosis, weak and rapid pulse, cutaneous eruption sometimes, subnormal temperature at times, convulsions.

Treatment consists in giving: emetics; rectal irrigation; cathartics or salines; morphine for pain (if necessary) heat and stimulants (strychnine, nitroglycerin, alcohol) for collapse; rest in bed; and gastrointestinal antiseptics.

13. *Insanity* is defined, in Allbutt's "System of Medicine," as "such a disorder or disease of the nervous system as prevents the individual from reacting normally as a member of the society to which by birth and education he belongs."

14. In *apoplexy:* There is generally paralysis of the head and upper limbs; and in left-sided lesions there may be aphasia; the pulse is slow and full; the respirations are at first slow, regular, and stertorous, later on becoming of the Cheyne-Stokes type.

In *opium narcosis:* The pupils are contracted; there is no sign of paralysis; both respirations and pulse are slow and full.

In *uræmia:* The coma is deep; the pulse slow; the respirations are frequent and irregular; the urine shows the presence of albumin and casts, with a diminished output of urea; there may be a urinous odor to the breath.

In *alcoholic intoxication:* The patient can generally be aroused; the coma is not, as a rule, complete; the face may be flushed; the pupils are normal or dilated; the respirations are normal in frequency, but deep; the skin is cool and moist, and the body temperature may be below normal.

In *epilepsy* there will be a brief aura, sudden and complete loss of consciousness, pupils dilated and rigid, the tongue will be bitten (unless prevented), the sphincters may be relaxed, there may be a slight rise of temperature.

15. *Malpractice* is a failure on the part of a medical practitioner to use such skill, care, and judgment in the treatment of a patient as the law requires; and thereby the patient suffers damage.* If due to negligence only, it is *civil malpractice.* But if done deliberately, or wrongfully, or if gross carelessness or neglect have been shown, or if some illegal operation (such as criminal abortion) be performed, it is *criminal malpractice.*

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. 5
Arizona*	Ancil Martin, Phoenix	Phoenix	Jan. 4
Arkansas*	F. T. Murphy, Brinkley	Little Rock	Oct. 13
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	Los Angeles	Dec. 1
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	Jan. 5
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Nov. 10
Delaware	J. H. Wilson, Dover	Dover	Dec. 8
Dist. of Col'bia.	Geo. C. Ober, Washington	Washington	Oct. 13
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	Nov. 11
Georgia	E. R. Anthony, Griffin	Atlanta	
Idaho	W. F. Howard, Pocatello	Boise	April 6
Illinois	J. A. Egan, Springfield	Chicago	Oct. 21

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular state.

Alabama.—At the examinations held in June and July there were 138 applicants; of these, 66, or less than one-half, were successful.

Indiana.—During the year 1907 State board certificates were issued to 190 physicians after examination. Nineteen failed to pass the examinations.

Connecticut.—Reciprocity is now permitted under certain conditions.

Washington.—At the July examination there were 145 applicants; of this number, 39 failed in the examination, and one withdrew.

Oregon.—At the July examination there were 67 applicants, but only 23 of these were successful.

New Jersey.—At the examination held at Trenton, June 16-17, 1908, the total number of candidates examined was 59, of whom 49 passed and 10 failed.

Wisconsin.—At the examination held at Madison, July 14-16, 1908, the total number of candidates examined was 66, of whom 60 passed, 3 were conditioned, and 3 failed. Eleven reciprocal licenses were granted at this examination.

THE DIAGNOSIS OF PEPTIC ULCER.*

By DUDLEY ROBERTS, M.D.,

BROOKLYN, NEW YORK.

VISITING GASTROENTEROLOGIST BROOKLYN HOSPITAL.

Considerable progress has been made in the diagnosis of gastric ulcer in recent years; it is true that no pathognomonic sign or symptom has been discovered, but we have learned that the classic picture is present only in the unusual case; we realize now that to demand this complete picture is to fail in the recognition of the large proportion of cases. The widest variation is symptomatology is expected and thorough exhaustive study of the individual patient is coming to be recognized as the *sine qua non* in diagnosis.

The typical case of peptic ulcer, in the history of which there is the complaint of regular pain after meals, tenderness in the epigastrium, vomiting occurring regularly with the pain, and blood macroscopically evident in the stool or vomitus, is not at all likely to be overlooked; such a syndrome is generally familiar, and the danger lies in the possibility of assuming the presence of ulcer incorrectly when the symptoms are superficially similar to ulcer symptoms but are actually different in important particulars. It is not the mere presence of this quadrad of symptoms which is diagnostic, but the appearance of these symptoms in a typical form. The characteristic form of these symptoms becomes then a matter of great moment.

The typical ulcer pain is that which develops from half to two hours after eating; begins not suddenly but develops somewhat gradually: it is burning, boring, cutting, or stabbing; is localized in the middle line close to the ensiform, possibly radiating to a degree into the back or up into the precordium; it is regular in its occurrence, coming after every meal when coming at all; it is more apt to be induced by the solid foods, rarely following the ingestion of water; it usually lasts for quite some time, often only to be terminated by vomiting, or the ingestion of an alkali or an albuminous food. Pain such as this is almost positively diagnostic of gastric ulcer even without other pronounced symptoms. As in one particular or another it deviates from this description, pain is less positively diagnostic until of itself it ceases to be even suggestive of this condition.

The tenderness in this type of case is pronounced, even exquisite; it is sharply localized over a small area in the middle line between the ensiform and a point midway down to the umbilicus. The more diffuse tenderness or such as may be found in other situations, has a diminishing degree of diagnostic value. The Boas tender spots in the back are frequently found in ulcer, but so commonly are such spots found in the neurotic, that their presence must not in my opinion be taken as strongly suggestive unless the tenderness in the epigastrium is also marked.

Vomiting, occurring as it does in only about fifty or sixty per cent. of cases, is not at all essential in the picture. In the type of ulcer under consideration it occurs only in conjunction with the pain, and usually not until the pain has become severe. Vomiting alone without pain cannot be spoken of as at all suggestive of ulcer except that form which occurs when the pylorus is stenosed; when this takes place there is either occasional profuse morning vomiting or a painless overflowing of the stomach after meals. Otherwise, vomiting which takes place ten to fifteen minutes after meals is to be attributed to acute protracted gastritis, ulcer or stenosis of the esophagus or cardia, psychopathic states, or cerebral lesions. Regurgitation is often mistaken for true vomiting, but the distinction is an important one, as regurgitation rarely evidences an actual gastric lesion, but usually esophageal stenosis or a nervous abnormality.

Actual hematemesis taken with these other symptoms is almost absolutely diagnostic; without pain or tenderness it has less of diagnostic value because its occurrence is not uncommon in conditions other than ulcer. Slow leakage from the gastric mucosa, as in passive hyperemia and severe anemic states must be considered, and the possibility of the blood having arisen from the respiratory passages, and been swallowed is sometimes presented. It is surprising what quantities of blood may come from a pulmonary lesion which occasions little or no cough; such blood when swallowed may be vomited either fresh or dark and clotted. In beginning miliary tuberculosis with few physical signs this type of bleeding may cause serious mistakes. The occurrence of a few flecks of blood in mucus or even a small quantity of bright red blood after prolonged retching is too common to allow us to draw conclusions from its occurrence; it has frequently happened that the tendency to base too much on the presence of very small quantities of blood in the vomitus has led to a diagnosis of ulcer when, for example, hysterical vomiting demanding absolutely different treatment has been entirely responsible for the appearence of the small quantities of blood.

Black stools while suspicious so often result from constipation and a meat diet that they should not be accepted as evidencing bleeding; when an intelligent observer insists that the stools have been tarry or purplish in color there is very considerable ground for suspicion. If the appearance admits of any doubt whatever, the proof by chemical test is absolutely necessary. A history of the passage of fresh blood with or after the def-

*Read before the Brooklyn Medical Society, March 20, 1908.

ecations can rarely be taken as an evidence of gastric or upper intestinl bleeding. Only on two occasions have I personally seen fresh blood from such a source, and in each instance the bowels were very active and the bleeding so severe that marked constitutional symptoms were developed.

A case presenting these symptoms and signs in the form described is one of gastric ulcer almost beyond the peradventure of a doubt. Carcinoma which has developed upon an ulcer may have to be eliminated by further study. Such a complete picture being so uncommon, the question arises as to the suggestiveness of individual symptoms, and the variation of these and other symptoms as yet unmentioned.

It is well agreed that pain is the commonest symptom which calls attention to the possibility of an ulcer in the stomach, but in its characteristics it frequently varies from the form described. When a pain is complained of in situations other than in the upper epigastrium it is not suggestive of simple, uncomplicated gastric ulcer. Sequelæ and complications may give rise to pain, not directly in the upper epigastrium, but even though the stomach is much enlarged or much below the normal position the pain of ulcer *per se* occurs well above the umbilicus and but little to the right or left of the median line. Diffuseness of pain speaks against simple ulcer as a cause.

In character the pain is frequently different from that previously described; it may be a localized heavy ache or a dull, boring sensation. It may occur only on infrequent occasions, particularly after a dietary indiscretion or a period of physical or mental strain. When attacks of pain seem only to follow periods of overwork or anxiety a diagnosis of a neurosis is very apt to be erroneously made. At such times the constantly present ulceration occasions discomfort either because of an increase of acidity of the stomach contents or because of the unusual irritability of the nervous system.

For no reason whatever that can be discovered ulcer may occasion no pain for long periods, and then suddenly give rise to great distress for a time. This seems to be almost characteristic of the chronic indurated ulcer as seen in those of middle life. The tendency is to consider that medical treatment has effected a cure when there has been a natural period of remission. Given an individual apparently free from psychopathic taint who for years has suffered from periods of epigastric pain alternating with periods of absolute freedom from signs of digestive disturbance or with only those of the mildest sort, the diagnosis of chronic ulceration of the stomach is highly probable, although there be no complaint of other symptoms. Formerly it was the custom to attribute such a complaint to hyperacidity, but stool examination during the periods of suffering have shown that there is bleeding from the gastrointestinal tract and exploration has frequently of late shown the presence of an organic lesion.

While the pain of ulcer is expected to begin one-half to three hours after meals, it is often more delayed, particularly when the ulcer is near or on the pylorus. Pain which occurs very late is, of course, more suggestive of a duodenal location of the ulcer. Sometimes the pain comes in sharp attacks, awakening the patient at midnight or after. Pain which occurs thus late after meals is usually spasmodic in character, coming and going rather suddenly and being very severe and cramplike in character. This sort of pain which is apparently the result of pylorospasm as the last of the stomach contents are being emptied into the duodenum, may also arise from other abnormalities, and the differential diagnosis may be a matter of great difficulty. The reflex pylorospasm from gall-bladder and appendix disease is much less apt to be regular in its time of occurrence, and definite signs and symptoms referable to the diseased organ are expected. Emotional states certainly seem to lead directly to attacks of pyloraspasm. When such an occurrence is frequent or recurs at a definite time without marked emotional excitement, an organic cause should be suspected.

Pain which is constant or complained of before breakfast in the morning, when the stomach is empty, is rarely due to a gastric ulcer; there may be slight constant discomfort even though the stomach is empty; this may be suggestive of ulcer, although not often met with. Pain which begins immediately or a very few minutes after food ingestion is also rarely to be attributed to ulcer except in those somewhat rare cases of ulcer at the cardia.

Tenderness is usually present early in the course of ulcer, but when a lesion has been present for some time, it is not at all unusual to find no tenderness whatever or only a slight degree during periods of apparent exacerbation. This is exceedingly important, as the classical teaching regarding *tenderness* in ulcer is quite different.

The tenderness is usually located sharply in the middle line high up in the epigastrium, possibly a little to the right or left. When an ulcer is situated directly beyond the pylorus or near the orifice and there is spasm of this sphincter, tenderness is discovered in an area which makes for difficulty in differential diagnosis. The small individual with a narrow chest presents a very small right hypochondrium for examination; within this small area there is much to tax the diagnostic powers of the surgeon and clinician. The presence of tenderness may indicate but little more than that one of a number of disease processes is to be dealt with.

Belching of gas has quite frequently of late been mentioned by the surgeons as an important symptom in ulcer of the stomach; in cholelithiasis it is said to be less constant. The clinician hears complaints of belching so constantly he is not apt to attach much diagnostic significance to its presence. On the other hand it is frequently not complained of at all by those afflicted with gastric ulcer. Belching of itself is not suggestive, and when belching is added to the history of pain very little is added to aid in the diagnosis.

Hyperchlorhydria is contributory evidence in the diagnosis, but as it occurs, according to the best investigations on this subject, in only about 55 per cent. of all cases, it is not at all essential to the diagnosis. Hypochlorhydria is not rarely found. Hyperchlorhydria, on the other hand, does not rule out carcinoma, for long after the malignant degeneration of an ulcer very high degrees of free acidity may be found. This is, of course, the very exceptional case, and any free hydrochloric acid is weighty evidence against carcinoma.

A word may here be interposed, regarding the belief held by many in times past and even the present, that true epigastric pain may be the re-

sult of hyperchlorhydria. As cases of this apparent nature are studied with care, it becomes doubtful that there is not usually a lesion of the mucosa which accounts for the pain. Hyperchlorhydria is a common condition; slight epigastric discomfort, acid eructations, and belching are frequent resulting complaints, but attacks of actual epigastric pain or severe burning localized in the epigastrium so strongly suggest the presence of ulcer or some form of abrasion that this is to be ruled out only by most careful study of the case. Attacks of pylorospasm are also to be looked upon as due to hyperchlorhydria in rare instances, if at all. Both pylorospasm and hyperchlorhydria are occasionally observed following immediately upon a period of intense emotional excitement. There is no reason why the pylorospasm should be attributed to hyperchlorhydria, as their association is not at all constant.

Hypersecretion is an even more constant finding in gastric ulcer than is hyperchlorhydria. The test meal extracted from a stomach which is affected by an ulcer is usually very thin and large in amount. There is nearly always a rapid separation of the extracted chyme into a whitish clear upper layer and a lower finely granular layer, the remains of ingested bread. Just how much gastric juice may be found in a normal stomach is a matter of dispute; it would seem that there should be practically none if conditions are actually normal and the tube is kept in the stomach but a short time. One hundred or more cubic centimeters of gastric juice in the fasting stomach is somewhat suggestive of a gastric ulcer and one near the pylorus causing at least partial obstruction. In other words, I am of the opinion that acute or chronic gastrosuccorhea is exceedingly suspicious of a chronic lesion of the mucosa and rarely to be considered a neurosis.

During the past few years, largely as a result of the excellent work of Boas and his pupils, and more recently of many investigators, the occult blood tests on stomach contents and stools have come into much deserved prominence. It is unquestionably the most important recent addition to our knowledge of the diagnosis of gastric and duodenal ulceration and the exclusion of those diseases of the upper abdomen which simulate ulcer. The same criticisms apply to these tests that have been offered as objections to other laboratory methods of diagnosis; they may be misleading if not interpreted by the careful study of the case; they may lead to mistakes if the greatest care is not taken in technique; they are fallacious unless certain sources of error are rigidly excluded. The taking of repeated test meals is objected to with good reason and the passage of the tube may be contraindicated by the features of the case. In ulcer of the stomach it frequently happens that blood is not found in the stomach contents while clearly demonstrable in the stools; the contrary, however, is not observed. It is for this reason that the stools are now relied on to show evidence of bleeding. If it can be shown or assumed that there is no addition of blood from the upper or lower respiratory passages, none in the ingesta, and none coming from the lower bowel, the presumption is in favor of a gastric or duodenal origin when symptoms indicative of trouble in this area are present. These tests are not so fine that the positive test can be neglected. Given the meat-free diet and free as well from such medicaments as are made from meat or blood, even the benzidin test, the most delicate of all, cannot be disregarded if positive.

Personal experiences with the routine examination of the stool for blood in all sorts of gastrointestinal complaints has convinced me of the value of such tests in differential diagnosis. Repeated examinations are frequently very necessary if we are to gain the full value from these tests. Single negative tests certainly mean very little. Repeated tests of the stools for occult blood often make possible an absolutely positive diagnosis of the obscure case of ulcer when it would otherwise be impossible without direct inspection. The effort to unravel the nature of an upper abdominal complaint should never be looked upon as completed until daily examinations of the stools for occult blood have been made for a period of days and even weeks during which all sources of error, such as meat in the diet, are excluded.

Gastroscopy promises to be of value in the occasional case, but it must be recognized that the upcurved pyloric area, the most frequent site of ulcer, must remain somewhat difficult of inspection. Duodenal ulcers can only in very rare instances be directly seen by this method. Gastroscopy can therefore hardly be looked upon as a procedure which is to exclude the presence of ulcer, although it may demonstrate that such a condition is present when not at all suggested by other clinical procedures.

Orthoform, as suggested by Murdock, is sometimes of value in the diagnosis, but it has been found that in some instances the pain of ulcer is not relieved by this drug, while occasionally the pain of conditions other than ulcer may be somewhat abated.

In the fact that a bland diet, such as the strict milk diet, is particularly apt to bring about a cessation of the pain and other symptoms of gastric ulcer even though it be of no permanent value, we have a distinctly valuable point in the diagnosis of the obscure case. Other lesions and the neuroses which occasion complaints in this area are much less apt to be thus favorably influenced by this quality of blandness in the diet. Forced feeding, on the other hand, which has such a salutary effect on many of the functional disturbances, is not at all well borne if there be an abrasion of the mucosa. This is often evidenced when the attempt is made to add solid foods to the dietary of the patient afflicted with ulcer who has for weeks taken a fluid diet without any disturbance of sensation.

In the diagnosis of gastric ulcer the importance, indeed the necessity, of prolonged observation is not to be forgotten. In this way the temperament and the peculiarities of the individual become understood, and to all complaints we are able to give a proper valuation. Unless it is evident that there is a lesion present which makes temporizing unwarranted, cases in any way suspicious of gastric ulcer should be studied with care for a long time. The patient should often be given to understand the difficulties of the diagnosis and the likelihood of apparent cures from long and dangerous periods of latency. The importance of again submitting to observation if there is any return of the trouble must be carefully explained. In this way only can we avoid being confirmed in our mistakes; as it is, in a large city the tendency is to see only the mistakes of our neighbor. In passing from the

observation of one clinician to another the patient is apt to be the loser, as the same ground is covered many times, the same mistakes made, the same unsuccessful treatment administered, and the same temporary relief taken to be a permanent cure. Frankness to all those who are intellectually able to stand it, is the remedy for much of this unsatisfactory state of things connected with the diagnosis of obscure upper abdominal disease.

THE RATIONAL TREATMENT OF SPLANCHNOPTOSIS:*

DISPLACEMENTS OF VISCERA, BOTH ABDOMINAL AND THORACIC.

By J. MADISON TAYLOR, A.B., M.D.,

PHILADELPHIA, PA.

This brief paper is intended to set forth personal experiences and methods used in treating displacements of the viscera. These disorders are exceedingly common, often unrecognizable except by inference, yet, even in their incipience extend causal relationships to a large number of disabling maladies. While it is occasionally possible for good health to be maintained in spite of maladjustments of any of the great organs, it is obviously essential that, to maintain organic competency, normality of anatomical interrelationships must be preserved. Medical literature is full of testimony to the hurtfulness of morphological dissociations in the hydrostatic mechanisms.

In pursuing researches while preparing former papers on allied subjects, the writer was constantly impressed with the clinical significance of displacements of viscera, especially the potency for harm which distortion of blood-vessels and connecting tubes exerts on visceral integrity and organic action.

Fatigability, all those conditions which evolve from lowered vitality, and the whole complex array of exhaustion states which complicate so gravely the problems of infection and form indices of prognosis, stand at the head of causal agencies. We may here outline a postulate on which to build our argument: that individual is most favorably qualified to exercise his autoprotective powers whose hydrostatic mechanisms are, and remain, the nearest possible to normal in position, elasticity, patency, etc. Conversely: that individual who suffers from whatsoever degree or kind of interference with the caliber of the tubular organs, blood-vessels, etc., stands in grave peril, the extent and character of which it is often difficult to estimate.

The causes of splanchnoptosis, movable, displaced, prolapsed, wandering or dislocated hollow organs, lie far back in the origins of growth and development. A neurasthenic tendency is the fountain source of all such defects. Some of these may be characterized as hereditary and others as acquired, but they are often so interwoven by evolution as to be etiologically indistinguishable. Clinically it is important to estimate how much is referable to accident or constitutional weaknesses from whatsoever source. A large part of those factors which are blamed for the initiation of the splanchnoptosis, such as digestive faults, intestinal putrefactions, functional derangements, errors during parturition, and the like, are usually, if not always, merely efficient or instrumental, not primary causes.

It is obvious then that the clinician must direct his remedial measures to the correction of the primitive defects, local or constitutional. By this course alone is it possible to achieve satisfactory repair.

To relegate these extremely prevalent, insidious, often most baffling but ultimately disabling disorders to the operating surgeon and be content with whatever perfection of mechanical replacement he can accomplish, is to fulfill but a small part of our intelligent duty. It must be admitted that the surgeon has given the subject that habitual thoroughness of practical study, within his jurisdiction, which is less noticeable among practitioners of medicine. To be sure, the surgeon enjoys the privilege of seeing, handling, and adjusting parts after removal of the obscuring envelope not vouchsafed to the physician. If we would justify the name of "internists" we must utilize our equipment in the same lines of anatomical, physiological, and pathological knowledge common to both. Our faults lie in depending too much on memory and not making adequate use of reasoning.

When the condition presenting is one of graphic obviousness, *e.g.* a markedly displaced stomach or kidney, undoubtedly mechanical replacement, "plication," or fixation is often the only course to be considered. When, however, the best that surgery can do has been done, there yet remains a multitude of organic faults of circulatory apparatus, constitutional damagements, and disordered nerve centers, original or acquired, which demand correction from the points of origin.

Whatever the sources of causation, and they are necessarily various, differing in degrees and directions of evolution, we have then to overcome cellular vitiation in several situations, among which are:

(1) Loss of nutritive vigor in the vasomotor subcenters in the cord, through which the affected parts are innervated and consequently,

(2) Impairment of nutrition in the internal structures which contribute to support; and

(3) Relative weakness in the external abdominal muscles.

There are also contributory sources of weakness to be corrected, such as loss of tone in the skeletal structures, vitiation of motor innervations, and in the whole cycle of the autoprotective powers, oxygenation, etc.

Oftentimes the patient will present such profound neurasthenic conditions—relaxation of the arterioles, exhaustion of the nerve centers, intense fatigability, physiological and emotional irritability, nutritive derangements, and the like—that it may be necessary to begin with a thorough and protracted course of rest treatment.*

Dietetic measures are of paramount importance and have been presented at length in previous papers. The chief dissiderata are, in treating the splanchnoptoses, to overcome intestinal putrefactions, especially by teaching how to eat and masticate, the use of lactacid milk, rational measures to overcome constipation, etc. Personally I cannot agree with the views expressed by so many that it is desirable to encourage collections of intra-abdominal fat with the expectation of thus affording support. One might as well use a jelly fish for a pillow.

Replacement of the prolapsed, wandering, or dislocated and fixed viscus should be performed by the physician himself. Later a masseur may do the routine work with safety, but only under supervision. Posture is helpful in securing replacement

*Read at the meeting of the American Therapeutic Society, May 8, 1908.

*See articles by the author, "The Conduct of Rest Treatment," Internat. Clinics, 13th Series, 1903; "The Essence of the Rest Cure," Monthly Cyclopedia, June, 1908, and "Repair of Will Loss," Internat. Clinics, Vols. II., III., and IV., 7th series.

and ultimate relative fixation. It is often well to keep the patient in a shoulder dependent, hip raised attitude for an hour or more at a time, inviting the cooperation of gravity. Several times I have relieved an agonizingly painful crisis by partly suspending a patient, placing a leg over each of my shoulders, half lifting him from the bed, meanwhile moulding the offending tissues and steadily, continuously, and forcefully applying taxis.

It is desirable frequently to assure oneself by palpation of the exact position of the viscus. Skill becomes instinctive. All lax viscera tending, as they do, to gravitate in an inchoate mass to the lower floor of the pelvis, it is essential to lift those systematically and repeatedly up and out from the lower quadrants of the abdomen. The subject lies in the dorsal decubitus, legs drawn up; the operator applies the hands one on top of the other to exert a steady force, drawing the underlying structures toward the umbilicus, and holding them there an appreciable length of time.

To replace a stomach, colon, liver, gall-bladder, cecum, sigmoid, kidney, or spleen, to say nothing of uterus and adnexa, is a nice operation demanding skill and power. An unusually large experience with masseurs convinces me that few can perform this act judiciously and even those require supervision and teaching. No disparagement is intended of the masseurs, for whom I feel the highest esteem. As they realize, few physicians have taken the pains to perfect themselves in their art as has the writer.

Incidentally let me mention that insomnia is often caused by an overfilled and dilated stomach, be it with fluid, air, or both. To empty this gives grateful relief and is often followed by instant sleep. Massage of the abdomen is powerful for good only if performed with a full appreciation of the varied, often diverse needs which must be met. Too often it is found useless and condemned unjustly. To appreciate all this, however, requires a degree and quality of knowledge impossible to be expected of any one but the physician.

Where there is pain due to pylorospasm, spasm of the common gall-duct, etc., vast comfort is often afforded by first employing steady pressure on the fourth to eighth dorsal vertebræ or adjacent tissues till the spasm is relaxed. From thence is the vasomotor innervation, and pressure relaxes the sphincters. The abdominal viscera are supported by the combined action of (*a*) the skeletal structures, (*b*) mutual adaptations among the structures within the cavity of the abdomen, (*c*) the diaphragm, (*d*) the omentum, and (*e*) the external abdominal walls. The skeletal structures should be put in good condition. This involves cultivation of all those factors which combine to maintain erectness. Stooping attitudes, slouching, encouraging depressions of those structures depending from the diaphragm, and the vertebral aspect of the abdominal cavity, especially an abnormal tilting of the pelvis, all invite confusion in the lower floor. Hence the first desideratum is to train the individual so to strengthen the massive muscles, ligaments, etc., that normal erectness shall become habitual. This can be done more decidedly by special education in promoting elasticity, in accurate adjustments, especially in securing full mobility and horizontality of the ribs, by forcible expiratory acts, than by the ordinary active sports or gymnastics. To attain this object my personal attention is given both directly and by supervision.

As a part of the pursuit of correct posture is the necessary training in full elasticity of all the muscles, movability of the ligaments and of junctures large and small, which is to be secured only by systematic stretchings, torsions, and other movements, both passive and cooperative. This is the only method of achieving the needed full motor power.

Development of the abdominal supports was the subject of a paper read by me before this Society May 4, 1907 (*N. Y. Med. Journal*, Nov. 6, 1907). No single measure is more capable of overcoming many baffling disorders of metabolism. Artificial supports to the abdomen, especially the invaluable belt devised by Morris Longstreth (to be described later), are indicated and should be used until there is full restoration of power to exert normal counterpressures, always essential to the maintenance of hydrostatic balance. There is much lymph stasis to be overcome, especially in muscles waterlogged as well as long disused, and often never properly developed.

To achieve this needed development is not easy. The subject is rarely sincerely desirous of radical improvement, at least not to the point of making the necessary continued efforts. We have to deal usually with individuals of feeble musculature, relaxed arterioles, marked fatigability, and habits of indolence. Their structures are all at fault, hence correct motor habits have suffered long neglect. The hollow viscera act through regular rhythmic peristalsis, of varying rates of speed. Rest is an important agency, definitely periodic rather than constant, but never too prolonged.

The most potent agent in overcoming the anatomical defects of the ptoses is to secure such a tone of the muscles of the torso that they shall not only recover their aforetime vigor, but become developed toward perfection. They should be made to reach the highest grade of efficacy which the inherent resources of the individual are capable of attaining, to resume not only what they were at their best, but become as good as they can be made. No muscles of the human body are so neglected as those of the diaphragm, the external abdominal muscles, and those involved in respiration. Systematic breathing exercises, even though they be clumsily and partially employed, produce gratifying results. When these are consistently taught and faithfully practised, this measure alone will establish a degree of invigoration of the whole economy which will satisfy the most exacting. The patient should first learn to draw the abdomen forcefully and deliberately inward and upward, next to combine this forceful indrawing of the abdomen and lifting up of the symphysis pubis with the act of expiration. This again should be combined with other simple muscle tensions by slow increments, such as flexion and extension of the wrist, of the ankle, of the shoulder girdle, etc. All acts should be a complex of respiratory, especially expiratory, emphasis plus simple increasing extensions or flexions of a limb, or portion of a limb. Along with this should be practised exercises promoting the elasticity of the flexures, the joints, especially the hips, the pelvis, the scapular muscles, also torsion movements, rotations, etc.

Among the difficult problems in relieving the splanchnoptoses is to secure suitable support for the relaxed abdominal walls. At best all artificial devices are but temporary measures, secondary to the radical restoration of the power of the tissues to perform their own duty, and they should be modified or abandoned when possible.

In a paper on this subject I pointed out the hurtfulness which ill-fitting girdles are capable of producing (*New York Med. Jour.*, May 11, 1907).

The only one which, in my experience, avoids most evils and supplies the right kind of help is that devised by Morris Longstreth, of Philadelphia. This consists of a belt, preferably attached to a corset, though it is useful for men and for some women without this attachment.

No girdle, belt, or special corset is of any permanent value which fails to compel the pelvis to remain on a normal level. Dr. Longstreth emphasizes one essential feature in normal standing posture: the shoulder, anterior superior spine of the ilium, external trochanter, and arch of the foot must fall within one vertical line. To achieve this the pelvis must be in its normal position, and this is accomplished by using his belt.

The desideratum is to secure a convenient, comfortable garment, readily adjusted, interfering as little as possible with esthetic requirements; it must support the abdomen fully, maintaining *in situ* organs which have been "replaced," or exerting a continuous assistance in the process of gradual replacement, whereby the intestines may regain their normal tone, caliber, direction, and affording relief to the organs, connecting ducts, and vessels from hurtful forms and degrees of pressure. It must simulate the natural support and pressure normally exerted on the abdominal contents; it must relieve increased weight when thrown upon the diaphragm and those structures which contribute to mutual organic support. It must not impair the normal excursus of movable parts, lower ribs, etc. It must not exert heavy, continuous pressure on paravertebral tissues, which causes excessive vasodilatation, hence chronic vascular relaxation and functional derangement in the organs or parts.

Most devices aiming to do all this unfortunately exert their force upon the soft structures of the abdomen in front and in the rear upon those above or near the sacrolumbar region and above the pelvic brim. The straight front corset is, in my opinion, most objectionable for reasons stated elsewhere. It invites, it practically compels the wearer to assume unnatural attitudes, especially a tilting downward and forward of the pelvis. The buttocks are pushed out posteriorly to relieve the pressure in front. It is a curious fact that women will eagerly welcome any special form of corset which promises to flatten the abdomen and squeeze the contents anywhere out of sight, no matter what the hurtful cost may be nor how deforming the effects. The effect of all straight front corsets is to tilt the pelvis down in front, exaggerate the backward thrust of the buttocks, and interfere seriously with normal plantigrade progression; it impairs the natural alignment of the body and throws strains upon the mechanisms which contribute to poise, hence economy of functionation. There is no question in my mind, after years of close attention to the damaging effects of faults in posture, that the nearer the individual achieves a level pelvis, *i.e.* a pelvis the plane of which stands at a practical right angle to a perpendicular vertebral line, the better. To be sure, the lines of beauty (displayed typically in the region of the hips and thighs) involve a moderate lumbar curve. The less of this, beyond that seen in a healthy, well developed young woman, the better. Not only is this the more beautiful attitude, but it more efficiently serves the purposes of Nature. The pelvis is a basin devised to contain the soft structures of the abdominal cavity. If it remains practically level these hollow, movable viscera stay where they belong. If it tilts downward in front these structures tend to pour out over the pelvic brim.

Any abnormality in the proper position of the pelvis is a serious factor in deranging the functions of structures lying within or immediately above, notably the appendix, Fallopian tubes, etc.

The belt devised by Dr. Longstreth is five inches wide, of extra firm webbing, the upper and lower lines parallel. No alteration is made in the parallelism (except where attached over the corset it is "worked in" by sewing). It encircles the hips from the "hip bone" (anterior superior spine of the ilium) to the "thigh bone" (external trochanter) which are ordinarily five inches apart; it is carried down in front to support the under surface of the abdomen. Thus the forces expended in sustaining the tissues of the torso proceed from the most solid, powerful structures in the body—those of the pelvic girdle, loins, and upper thighs. The effects of this firm horizontal encircling are to compel the pelvis to remain on a normal level, the back bone vertical, and for the patient to preserve habitually the erect posture. A corset alone, even of the straight front pattern, encourages relaxation of the back muscles. The combination of belt and corset enforces erectness, in both sitting and standing.

The belt is open in front, continues with the corset opening, and is fastened with three or four broad hooks. Behind it is also open, about three inches apart, adjusted with four strong tapes and buckles; no continuous pressure should rest on the paravertebral tissues. It is an index of normality in these muscles that they shall be free from adhesions to the subcutaneous tissues. A shrinkage in body girth is often rapidly effected, along with a replacement of the displaced organs and tissues. No offensive perineal bands are required to keep this belt in place. It will support equally well a thin or a pendulous abdomen. Most other girdles or belts lie above the hips, exerting too severe and constant a pressure on the lower back and belly; they are not steady; they tend to slip or pinch. It is most important, as has been said, to elicit the cooperation of the heavy muscles of the upper thighs. By this means the parallelograms of force are made to radiate upward and inward toward the vertebral line, obtainable in no other way. This belt by securing the pressure from these powerful hip and thigh tissues tends to lift the entire corset. Hence not only is there no constriction exerted on the waist, but the movements of the lower ribs become far more extensive and rise well above the pelvic brim.

When once the wearer becomes accustomed to this belt the comfort is complete. Nevertheless, much skill and judgment are required to attain individual adaptabilities. It is an artistic garment, only of service when nicely applied. Many careful fittings and progressive refittings are demanded, otherwise it may be unjustly condemned. The muscles must become adjusted slowly and progressively. There are always changes in shape, contour, alignments, and poise, as the normal attitude is approached. At first nearly all patients condemn and would reject the belt, but, with tactful persistence, they are finally led to accept it and, when needed, welcome it gladly. My own experience with it engenders enthusiasm for this device in ameliorating a variety of conditions not at first obviously related causally, among which are dyspepsia, loss of motility, venous tasis, dilatations, constipation, and obesity; especially those morbid states which the gynecologist finds rebellious, protracted, but not always demanding radical operation. It is of the utmost efficacy in regulating splanchnic circulation, relieving many cardiac diseases and derangements, and removing the passive hyperemias which are the chief causes of so much functional derangement.

In that group of obscure yet serious derangements caused by splanchnic arteriosclerosis it is peculiarly valuable. Often these are unrecognizable; inexplicable yet extraordinary improvement in vigor following the prolonged use of the belt may well be ascribed to the restoration of tone in the abdominal blood-vessels.

The measure to which I desire to direct final yet chief attention, one which has proved for me of greatest efficacy (although no logically contributory measure should be omitted) is the potentialities evoked by manipulating the paravertebral tissues with the purpose of so stimulating the vasomotor subcenters that the activity of the local circulation shall enhance nutrition in the disaffected structures. While this agency has been recognized and employed for nearly a century, as shown historically and outlined physiologically in a recent paper by my friend Seymour D. Ludlum (*Jour. Am. Med. Ass'n*, May 2, 1908), we have learned hitherto little more than empirical facts. In so brief an article it is only possible to assume the certitude of the physiodynamics involved in the reflex stimulation of viscera and supporting structures through hand pressures directed to the paravertebral tissues which are innervated by the posterior primary divisions of the spinal nerves, as set forth in other papers ("Diagnosis in Diseases in Children," *British Journal Diseases in Children*, January, 1905). (Hypothesis on the Etiology of Scoliosis, Monthly Cyclopedia, Vol. VIII., p. 303, 1905).

A rapidly accumulating experience, both personal and other, in the treatment of many protracted disorders, involving many instances of hitherto incurable organic derangements, has abundantly proven the efficacy of this form of manipulation in diverse fields of usefulness. In brief, so far as the correction of the splanchnoptosis is concerned we have to deal with depleted nutrition of the whole organism, but particularly in the parenchyma of the abdominal organs, along with pronounced impairment of functional activities, which act as secondary causes of distentions, dilatations, obstructions to local circulation, and these in many ways retroact also upon the supporting structures. Much of the disability is due to vascular stasis, waterlogging, the effects of retained toxins and toxic wastes on circulation and thereby constricting blood-vessels unduly. The object to be attained is to activate the total circulation both directly and generally. While many of our reliable drugs accomplish this in part, alone they often fail, whereas it will become obvious to any one, even to the scoffer, that manual treatment can and does rapidly and efficaciously improve circulatory activity, hence nutrition.

This is neither the time nor place to unfold the argument, but rather to indicate what to do. It is my custom to perform this spinal manipulation myself at least two or three times a week. It occupies about five to ten minutes. Not only does this measure bring about swift, patent, and permanent results, but oftentimes by other well chosen manipulations I am able to relieve many sensory irritations. If there are local congestions, inflammations, acute toxic irritations, etc., gentle continued pressure near certain vertebræ, inducing lessened tension in hyperemic areas, through sympathetic vasoconstriction, materially expedites removal of stasis.

In conclusion let me express the conviction, based on some experience, that, by the rational treatment of the splanchnoptoses or those diverse neurasthenic conditions in which it is safe to assume they are latent, we can rescue many invalids from lives of misery or from cruel limitations.

THE PERSONAL FACTOR IN DISEASE.

By BEVERLEY ROBINSON, M. D.,

NEW YORK.

The personal equation in disease seems to me, at present, to be of more real importance in practice than anything else. Formerly, this was thought to be true and emphasized in several ways. To begin with, the old practitioner was believed in for more than one good reason—but his powerful hold on the family was due essentially to the fact that it was believed and recognized that he knew all about it—that no individual peculiarity or idiosyncrasy escaped him. This was true in both health and disease. Hence they (the members of the family) always did, so far as practicable, what he advised, and they prized the advice most highly and loved and revered the giver of it.

From watching keenly and very carefully, during long and patient years of service, many patients, young and old, in all classes and conditions of life—and long before laboratory research work was known, or even thought of—arose a conviction that people could be grouped in classes in health, and thus sickness studied and observed. These classes had different temperaments, and among the temperaments there were, also, marked individual characteristics, and these, again, should be regarded and estimated collectively. These collections were grouped in large numbers and labeled with the term "diathesis." Now, diathesis is not one; it is several. It means constitutional peculiarity or individualism, as influenced by habits, professions, exposure, ambient conditions, food, drink, medicines, worries, anxieties, work, play, etc.

Among the diatheses, notably, were found: 1. The rheumatic. 2. The gouty. 3. The lymphatic. 4. The nervous. 5. The bilious. These names meant more and differently than they mean to-day—and much of what they tried to teach was wrong, or exaggerated. On the other hand, there was a kernel of great truth; there was a factor influencing, powerfully, certain individuals, and capable of becoming pronounced and influential on slight provocation, very frequently. Illustrations of these statements could be given which would be very numerous, widespread, and proceeding from the daily life work of every practitioner, general or special. I shall give a few to illustrate my affirmations, and among them are some which are familiar to many—perhaps to all.

Take an individual of the so-called rheumatic type. Let him be exposed for a short time to marked dampness, or let him get a casual wetting, or sit in a draught, or sit with wet shoes, and very soon he may and will give evident signs of rheumatism—such as pains, or aches in the joints, muscular stiffness and soreness, pain on pressure, or motion in certain parts, sometimes without fever, sometimes with. Again, take a gouty subject and let him make excesses or errors of diet; let him become thoroughly tired through overwork or anxiety; let him indulge freely in wine, beer, or spirits, and very soon his big toe will become red, swollen, and painful, his urine very light in color, of low specific gravity, but on cooling throwing down a marked deposit of red sand—or again he will pass a muddy, reddish fluid of high specific gravity, in diminished quantity. This urine, on boiling, will very soon clear up and appear normal and healthy by reason of solution of the contained urates.

Witness a pale, pasty-looking, phlegmatic young man, or woman, whose skin is dirty-looking, punctuated with little black specks (comedons), or having here and there reddish blotches, or swellings,

and here and there, perhaps, on the side of the neck a disfiguring, depressed scar, which shows where a former small abscess had opened and allowed pent-up pus to escape. These patients tire easily, are subject to catarrhal disorders of throat and nose, have coated tongues, foul breaths, constipated, or irregular bowels. They are notably improved, or helped whenever they can take salt baths and sojourn at the seashore for a prolonged period. They are especially helped by medication with cod liver oil and hypophosphites of lime and soda—iron may or may not be useful. Nutritious and abundant food of varied nature, properly prepared, is essential to their wellbeing. Little by little and with increasing years, when under proper care and treatment, they improve and outgrow acute manifestations of their constitutional defect, unless the provocation to it be very marked and important.

Now, aside from the general dyscrasic conditions which are clearly defined and evident to the experienced practitioner, there are many instances in which some accidental cause, or causes, some interlocking of different circumstances, short or long continued, may bring out symptoms, or signs which seem without much doubt to make the underlying constitutional state probable, or even tolerably clear.

In many individuals, however, there is no dyscrasia of any kind that can be shown, or that seems probable from any symptoms, or conditions, noted, or observed. And yet such individuals, and they are the vast majority of men, women, and children, have their pronounced peculiarities, idosyncrasies, reaction to, or effect caused by, some special food, or drink, or combination of divers foods in the form of prepared dishes. Again, as I have said, exercise, worry, heat, tire of mind and body may bring out symptoms and signs in one individual and not at all in another. Medicines, as we know, act very differently and sometimes alarmingly in different patients, and we have absolutely no means of knowing in advance frequently, why, or in what manner, they cause these occasionally untoward and unexpected effects.

As regards drink, I have known a tumblerful of milk bring on an attack of asthma with hives in an otherwise healthy child. When the milk was taken and a piece of bread eaten at the same time, there was no asthma and no hives. I could explain this by saying that the bread helped break up curd and that stomachal digestion was not interfered with. But why and precisely in what manner and for what reason asthma and hives were occasioned are certainly matters largely of thought and conjecture. I have known mushrooms in good condition and on repeated occasions cause most distressing edema of the uvula and palate. Prior to these attacks the same individual had eaten mushrooms repeatedly with no bad or unpleasant effects at all and had always thoroughly enjoyed them. I have known an individual in whom a single strawberry would give neuralgia of the teeth which lasted twelve to twenty-four hours. Again, prior to the attacks of neuralgia of the dental branches of the fifth nerve, the same individual had eaten repeatedly and abundantly of strawberries without pain, ache, or unpleasant symptoms of any kind. In this case it seemed as though the only plausible, though not entirely satisfactory, explanation was that with increasing years strawberries had become inimical to that patient.

Some anemic girls are kept awake with coffee; some go to sleep after taking coffee. No appreciable difference is noted between the girls who sleep and those who remain awake. The best one can say is that their temperament differs, and yet when we say it we do not really know what we mean, but cover up our ignorance with a big word. I have been called to a very alarming condition of syncope, followed by paralytic symptoms in the limbs and disordered cerebration, occasioned by two grains of quinine, when absolutely nothing else seemed rationally to account for the condition. Coca has been to me more than once the most powerful cardiac stimulant I could use. The same preparation with others under apparently similar conditions had little or no effect, good or bad, so far as I could determine.

I have known very large doses of nitroglycerin to be given experimentally in a healthy individual, and again where there was evidence of arteriosclerosis, and no appreciable effects were produced in either case. No throbbing of head in the one, no relaxation of arteries or head symptoms in the other. Many preparations of digitalis seem at times relatively inert, and yet the drug itself may have come from a well-known, honorable pharmacist. And thus I might further multiply example after example.

Undoubtedly with time the body of man changes, and changes, as we all know, to the effects of food, drink, medicine, exercise, etc.

We all discover these facts sooner or later if we watch closely, intelligently, and with proper training. It is to the wise physician to be guided and directed by this acquired knowledge so as to be most useful to his patient. And so it is with every new drug, every new combination of drugs; one must be extremely careful and give small, very small doses, until one has gauged properly the personal equation of the individual.

And so it is again in regard to mere pathological lesions. One man will carry a lesion for many long years without distress and almost with impunity which to another is rapidly fatal. Further, lesions found post-mortem are of such a character that we fail to comprehend how long life and its enjoyment were compatible with their existence—and yet they were. On the other hand, the closest scrutiny, the most minute investigation at the autopsy, and later in the laboratory, fail to discover the cause of a life-long suffering and misery, or adequately and rationally to explain the cause of death.

We must believe, therefore, that a wise, judicious empiricism in the way of caring for patients, in administering drugs, in trying to relieve symptoms and perhaps cure disease, is thoroughly allowable and desirable, and this despite all of the advances and teachings of the most recent scientific methods of research.

Many times we have seen, all of us, syphilitic lesions of horrid type and affecting deeply and in most aggravated ways most important organs, and yet we have known them to disappear almost magically with the use of mercury or iodide of potassium properly given, and sometimes, also, long continued.

Most pernicious and deadly malarial poison is undoubtedly cured with bark and its alkaloids, and that, too, when seemingly indelible evidences existed of its presence and passage. But why in either case do these results obtain? Little by little we believe we have reached in a measure the explanation, but final truth is, even in these best known instances, not yet attained altogether, as I humbly believe.

ABSCESS OF THE LUNG FROM ASCENDING INFECTION FROM APPENDICITIS, WITH REPORT OF CASES.

By J. N. HALL, M.D.,

DENVER, COLO.

Although the rupture of amebic abscess of the liver through the lung, with expectoration of its contents, is a well-recognized and not rare clinical condition, I have been surprised to find that a similar mode of emptying of a liver abscess arising from an appendical infection is sometimes not taken into account by even well-qualified members of the profession nor mentioned in many excellent textbooks. The exhaustive work of Kelly upon the appendix makes no note of it, further than a single line stating that an abscess may rupture into a bronchus, no hint being given that an extensive cavity in the lung substance may be formed. Much space is given to subphrenic abcess in this and other works, and empyema is frequently mentioned as a result of appendicitis, but of the lung itself little or nothing is said. Perhaps one reason for this lies in the fact that much of the writing on appendicitis is done by surgeons, while the lung abscess from this source comes to the physician oftener than to the surgeon, perhaps after existing a year or two, and often without a hint of its true origin excepting upon pointed inquiry, as in Case III.

Eisendrath, in a recent comprehensive article upon subphrenic abscess (*Journal of the American Medical Association*, March 7, 1908), states that "rupture of the subphrenic abscess into the lung has been reported in 19 cases." In some cases of the kind we are studying I feel sure that no definite abscess formation occurs beneath the diaphragm, but an inflammatory union between liver and diaphragm, diaphragm and pleura, and finally pleura and lung successively, with almost direct propagation of the liver abscess into the lung substance, and thence into the bronchus.

I wish to report three cases of extensive cavity formation in the lung from this cause, and shall associate with them reports of liver abscess and various other conditions which throw much light on the general subject.

Much stress is laid on septic embolism as the means of carrying appendical infection to other parts of the body. Doubtless this is a prominent factor in the spread from the radicles of the superior mesenteric vein about the cecum and appendix, upward by way of the portal system to the liver. Propagation by contiguity and extension of the inflammation directly from liver or subphrenic space to right pleura, left pleura, or pericardium is the rule—and in the great majority of cases to the right pleura, as we should expect.

The recognized origin of brain abscesses and other embolic conditions from suppurative processes in the lung makes it reasonable to assume that the late troubles noted in Case I were brought about in this manner by septic emboli from the wall of the cavity.

A strong argument for the removal of an offending appendix may be based upon the fact that the appendical inflammation, the first link in the pathological chain we are tracing, may be so slight in some instances (as in Case III herewith reported) as to fail to attract the physician's attention. Eisendrath states that "subphrenic abscess may follow an attack of appendicitis in which there has been no suppuration in or around the appendix." The serious results in Case V, where three minute ulcerations of the mucous membrane of the appendix had evidently been the starting point of a fatal illness which produced most of its symptoms far from this point, are worthy of note. It is far better for the patient to remove the appendix after the first definite attack, even though it show but comparatively slight pathological changes, than to allow it to remain, having the trivial or even almost imperceptible ulceration which may be the starting point of such troubles as we are discussing. The liver and lung complications are far more frequent in cases which run for some time unrecognized or without operation, and the fear of them should lead to prompt and intelligent action when we can recognize the early steps of the process.

In this region appendical lung abscess is apparently much less frequent than the amebic variety, for I have seen more than twice as many of the latter as of the former in Colorado. The number of my cases, however, is far too small to base judgment upon. In regions where amebic dysentery is more common, the disproportion in favor of amebic abscess would doubtless be very much greater.

Case I.—J., male, 28 years of age, seen with the late Dr. Parkhill, July, 1899. He had had an attack of appendicitis two and a half years before, and a second one a year later. In this attack an abscess formed, and was opened late. Within a fortnight or so he had a pain in the right side and lower chest, cough, and, beginning suddenly, the expectoration of many ounces of fetid pus daily. This had continued since. He had lost about 30 pounds in weight.

We found the appendical region negative excepting for the scar. An induration existed up toward the liver margin, and the liver was slightly prominent about the region of the gall-bladder. We found no evidence that the latter had ever been involved.

The right thorax was contracted so that the patient was bent laterally with the concavity to the right, as I have seen after amebic abscess of the liver and right lung. There was dullness over the lower right chest, with signs of a large cavity under the right nipple. The heart was displaced two inches to the right of its normal position, evidently from the shrinking process about the cavity.

About two ounces of offensive sputum was being expectorated daily, containing pus, elastic fibers, and many cocci. The urine had a trace of albumin and considerable pus. I think a pyelitis probably existed on the right side, but my notes are not complete upon this point. A letter just received from his physician, Dr. E. C. Baldwin, states that this patient had the right leg amputated above the knee for some septic trouble three years ago, and has since had abscesses of the arm, and later of the wrist. He has very rapid heart action and great dyspnea, but retains his weight. I infer that the infections have been embolic in origin, presumably from the lung process, which is still apparently more or less active.

Case II.—J. S. T., 42, married, laborer. Entered the Arapahoe County Hospital July 27, 1899, in my service. On February 1 he had had a painful abdominal trouble, and was sick for three weeks, presumably his first attack of appendicitis. May 1 he had a sharp attack, with abscess formation, and was operated upon ten days after at St. Joseph's Hospital by Dr. W. S. Bagot. Very slow recovery. Pain below ribs on right side was severe, and he was told by a physician that he had gall-stone colic. Moderate fever persisted, and soreness was pronounced over the liver region.

On July 30 I examined him at the hospital. Above the usual scar of the operation there was tenderness to the upper border of the liver, with

much induration below the edge of the ribs, and dullness on percussion. The lower half of the right chest was dull, merging into flatness below the eighth rib in the back and the fourth in the front, with decreased respiratory sounds and occasional wheezing râles. The usual signs of a cavity were found between the right nipple and the liver when he was examined after free expectoration. He was expectorating about eight ounces daily of thick, yellow pus, less offensive in odor than in some of the cases reported. The urine was negative. The temperature reached 101.5° once, but generally did not exceed 99°. The pulse was at different times as high as 108.

He gradually improved during his six weeks' stay in the hospital under tonic treatment, and gained in weight, the expectoration lessened, and the firm, dull mass in the upper right abdomen largely disappeared. He still had the signs of a cavity on discharge, and the cough and moderate expectoration persisted. I saw him two or three times during the next year. His condition was about that of a tuberculous patient with a quiescent cavity. He finally disappeared, and I cannot learn his further history.

Case III.—Male, 34 years of age. Seen with Dr. E. M. Brandt on January 27, 1908.

Fifteen months previously he had evidently had a sharp attack of appendicitis, followed by chills and septic temperature. About eight weeks after the beginning of the attack, a rib was resected above the liver, his physician in an Eastern State believing that he had empyema. No pus was found. Two days later he began coughing up pus of a most fetid character, and is still, after more than a year, raising a pint a day. His wound was reopened six months later, but nothing could be done.

We found that he had lost fifty pounds of flesh. He was moderately rigid over the right abdomen. Liver apparently negative in front. Over the right back there were dullness and decreased respiration to the tip of the scapula and the right posterior axillary margin. Many colon bacilli in sputum.

Drs. Brandt and McGraw opened up the old wound, and found a large cavity in the right lower lobe communicating below with a sinus in the dome of the liver, and above with a large bronchus. Free drainage was established. Old dense adhesions existed about the appendix, but no abscess was found there. He did fairly well for some weeks, when an attempt was made to collapse the ribs over the large cavity, since it seemed that it could never heal. The patient died shortly of shock and exhaustion.

The following cases of ascending infection from the appendix, but not causing abscess of the lung, are of interest in this connection:

Case IV.—K., female, eight years of age, seen with Drs. C. B. Van Zant and Leonard Freeman in 1902. Following an obscure abdominal disease, she had been operated upon in the East for empyema of the right side, and now, after coming West to recuperate, had an abscess encysted behind the navel, between the intestine and the abdominal wall. This was opened in three places and drained. Dr. Freeman found the old thickened appendix with a dense mass of adhesions running upward toward the liver, which had obviously been the cause of the ascending infection causing the empyema. In this case the connection between the appendical inflammation and the pleural trouble was not suspected until the discovery of the adhesions about the appendix.

Case V.—Mrs. B., 24 years of age, seen with Drs. Swerdfeger and Tennant. Several mild attacks of appendicitis during the past four years. Has had the usual signs of a new and more severe attack for nine days, with temperature upwards of 102°, pulse over 100, pain, rigidity, and tenderness. We found marked pericardial friction, and the next day, rough, dry pleuritic friction over the lower right chest. Much pain and soreness were found in both locations and over the liver.

A chronically inflamed appendix was removed the next day, with three small ulcers showing upon the internal surface upon section. We had expected to find an abscess here, but found none. As in some other cases I have seen, the inflamed appendix was doing much less harm than the severe ascending infection which it had originated. The patient died, thoroughly septic, some four days later. The involvement of the pericardium is rare enough to deserve careful attention. We were much disappointed in being unable to locate a pus cavity above the appendical inflammation, but the septic infection carried the patient off before such a localization could take place.

Case VI.—M., female, 6 years old. Seen with Dr. L. Freeman, October 20, 1905, at St. Joseph's Hospital. She had a typical attack of a severe appendicitis, beginning seventeen days ago, diagnosed and treated by Dr. Wheden, of Monte Vista. Although it was believed that the attack had subsided, the temperature still reached 102° to 103° daily, and she had the chills and sweats of sepsis. We found a subphrenic abscess containing air and foul pus, with tympany and changeable dullness. Dr. Freeman resected a rib and drained it, and later opened an abscess in the liver. She recovered slowly but fully.

Case VII.—M., 60, male, seen with Drs. Sewall and Freeman, December 23, 1905, at the Denver City and County Hospital. He had an immense right subphrenic abscess from an ascending appendical infection, which was opened and drained successfully by Dr. Freeman.

Case VIII.—Mrs. S., 30, seen at Mercy Hospital with Drs. C. K. Fleming and E. H. McGill, March 18, 1908. She has had two attacks of appendicitis during a recent pregnancy, the second one bringing on labor at the sixth month, this occurring six weeks ago. She has now chills, sweats, pain over the liver, temperature of 103° daily, and a large, tender liver. The spleen is palpable. No sign of disease in the pelvis, nor in the chest, excepting occasional cough.

Dr. Fleming removed the puckered and shrunken appendix from a mass of dense adhesions. The liver was mottled in color and softer than normal. No pus could be located by aspiration. A dozen gallstones were removed from the gall-bladder, but there were no adhesions nor thickening of its walls to suggest any severe infection.

A month later she was still in a condition suggesting septic anemia; there was jaundice of varying intensity, with a somewhat enlarged liver, transient but perfectly distinct pleural friction over the lower right lung on two occasions, and some pain and cough. We regarded the case as an instance of purulent infection of the liver from the appendical disease compressing the gall passages, while the upward extension involved the pleura. On April 28 the jaundice and pain had disappeared, the temperature and pulse were normal, and she seemed on the way to complete recovery. If an abscesss existed, it evidently discharged without our knowledge, presumably through the bowel or gall-passages. She went home apparently well May 1. Within a week, after a short febrile attack, pus was discharged in a fecal movement, and from the incision over the liver. She is now apparently well.

Case IX.—Male, miner, examined once only at

St. Anthony's Hospital, March 27, 1908, with Dr. Thomas H. Hawkins. On February 6 he states that he had abdominal pain, vomiting, fever, retention of urine, and soreness in lower right abdomen.

He now has a septic type of fever, pulse rising to 108, rigid abdomen, great tenderness over the appendical region, and upward towards appendix upon rectal examination. He had dry pleural friction at the left base five days ago, not found at my examination. The liver is moderately enlarged and tender. There was a dullness at both bases behind, with decreased respiratory sounds. No jaundice; spleen easily palpable; marked leucocytosis; operation advised, but declined, and the patient disappeared and cannot be traced.

This case is not conclusive, but extremely suggestive of the same pathological process we have been studying. Peptic ulcer and pancreatic disease would be difficult to exclude without operation. It is obvious, I think, that the large, tender liver, with involvement of the base of the lungs, the pleural cavities, or both, following an abdominal infection, points toward infection, and in just such cases abscess of lung may easily arise. The left-sided pleural friction would strongly suggest pancreatic disease, or gastric or duodenal ulcer, infecting the lesser peritoneal cavity and extending thence upward through the diaphragm, a condition I have observed before. Yet, as in Case V, the pericardium may be involved in appendical disease and the left pleura might as easily be affected.

Case X.—S., 23, male. Seen January 26, 1903, with Drs. Conroy, Miller, and Hawkins, at St. Anthony's Hospital. He had been operated upon four weeks before, forty-one hours after the beginning of the attack, for a sharp appendicitis, a pint and a half of seropurulent fluid being evacuated from the appendical region. The wound was closed without drainage.

A week later he had dry pleuritic friction over the region above the liver, and dullness extended to the tip of the scapula. The liver was enlarged, and we thought it contained an abscess. Dr. Hawkins found upon operation that the pus was beneath the right lobe of the liver, crowding it upward, and recovery followed free incision and drainage.

Case XI.—F., male, 41 years of age, seen with Drs. Freeman, Hawkins, and Fleming at St. Anthony's Hospital, March 7, 1902. Thirty hours after the beginning of his first attack of appendicitis he was operated upon, the appendix being found gangrenous and perforated. He had all the signs of an intense sepsis with gangrene of the edge of the incision, and died on the fifth day. Jaundice appeared the day after operation, the liver dullness practically disappeared, leucin appeared abundantly in the urine, with albumin and many hyaline, granular, and epithelial casts. Hiccough and delirium were noted. We concluded that death was directly due to acute yellow atrophy of the liver, but we were not able to obtain an autopsy.

Case XII.—M., aged 19. Following perforation in a virulent attack of appendicitis, an abscess was opened in the appendical region, another of the upper abdomen on the seventh day, and three days later yet another of the abdominal wall over the liver. Jaundice was present; death resulted shortly. The appendical inflammation may have been of typhoid origin in this case. There was no evidence of direct suppurative involvement of the liver, but there can be no question, I think, of a virulent ascending infection from the inflamed appendix.

Case XIII.—A., ranchman, seen with Dr. Leonard Freeman. He had had an attack of appendicitis five months previously, but was not operated upon. Three months later Dr. Freeman opened an abscess in the substance of the right kidney, which was still discharging when I saw him.

He was having chills almost daily, temperature ranging up to 103°, liver greatly enlarged and very tender; leucocytes 11,000; a motile bacillus was reported in the urine. The right kidney was opened again, and many pus cavities were found in its substance. The liver was explored, but no abscess located. The kidney was removed two weeks later, as the suppuration had destroyed it. At the post-mortem examination a few days later we found disseminated abscesses throughout the liver.

Case XIV.—Y., 42, male. Seen with Drs. Thorp, Greedy, and Perkins at St. Luke's Hospital, October 19, 1906. Following a sharp attack of appendicitis, four weeks ago, he has had pain over the liver and lower right lung, and now has chills and sweats and a septic temperature; leucocytes 40,000.

Dr. Perkins opened an abscess of the liver found by inserting a needle three inches below the tip of the right scapula. The pus was full of colon bacilli and had the familiar odor of this infection. A second operation was demanded two days later because of an abscess between the liver and the appendix, but the patient succumbed to general septic infection after three days. At the post-mortem examination the communication between the appendical abscess and that in the liver was easily demonstrated.

In several cases I have seen pneumonia after operation upon the appendix, but due, I believe, to the anesthetic or to mere chance, and not at all to a direct infection ascending from the abdomen. In several gynecological cases I have seen pneumonia or empyema follow an ascending infection, while in one such case we assumed that the pneumonia of the lower right lobe was embolic, because embolism also occurred in the left eye, with loss of that organ.

The constant affection of the lower lobe of the right lung in the cases we quote is sufficient evidence to me that the infection is usually conducted to the pleura and lung by direct contiguity, and not by an embolic process, as might well be assumed to be the case, for instance, should the upper left lobe be involved.

I think we may conclude that abscess of the lung is not infrequent in neglected cases of appendicitis, and that a cavity may remain for a long time after the abscess has emptied through a bronchus. The absence of the usual color of the pus of amebic abscess of the liver, of the history of dysentery, and the presence often of a definite colon bacillus odor to the expectoration lead us to think of the appendical origin of the trouble. The attack of appendicitis may have been unrecognized, but questioning will establish a plain history in many cases.

The bowing of the patient with concavity toward the right is not at all pathognomonic of lung involvement, either appendical or amebic, since I have seen it occasionally when dense adhesions had formed about an opened appendical abscess, and in other diseases of the right side of the abdomen. The position assumed reminds one of that in certain chronic cases of sciatica.

The prognosis is grave in cases of pulmonary involvement. Operation should be carefully considered. The chances of recovery must be doubtful at best, I believe, and we may accomplish much more by striving to avoid the complication than by attempting its cure. Although in any case we may have hepatic and pulmonary complications, in most cases they result from disregard of the early indications for operative intervention.

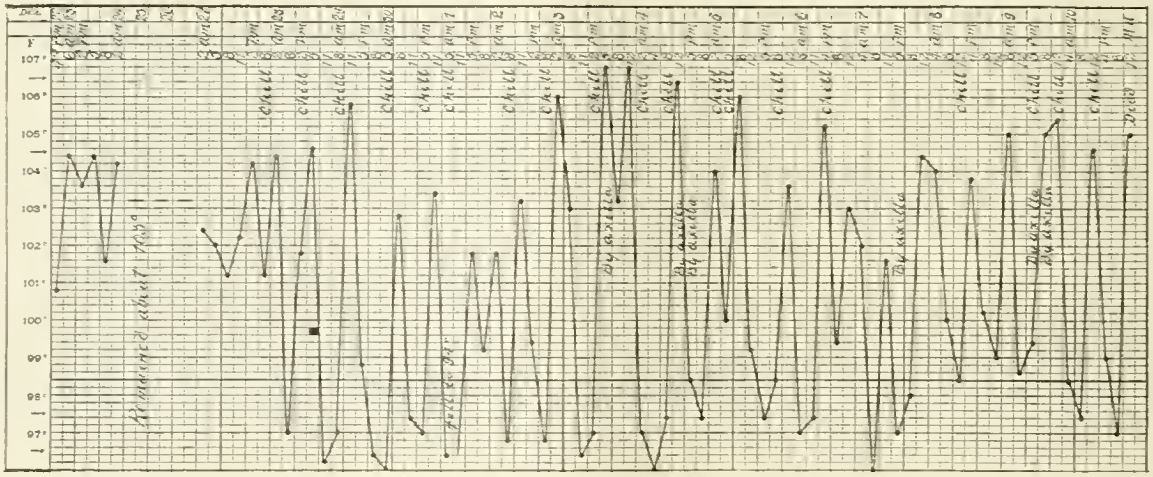
GONORRHEAL SEPTICEMIA, WITH MARKED CARDIAC INVOLVEMENT.*

By JOHN D. THOMAS, M.D.,

WASHINGTON, D. C.

PROFESSOR OF PHYSICAL DIAGNOSIS, GEORGETOWN UNIVERSITY MEDICAL SCHOOL; VISITING PHYSICIAN TUBERCULOSIS HOSPITAL; ASSOCIATE VISITING PHYSICIAN GEORGETOWN UNIVERSITY HOSPITAL AND EMERGENCY HOSPITAL.

Endocarditis has undergone a gradual evolution since 1824, when Bouillaud showed it to be a distinct disease with the pathological lesion in the heart valves or walls. Its relation to rheumatism and pneumonia, and the presence of pyemia in some cases was also recognized by him. Klebs, in 1878, recognized all forms of endocarditis as having their etiology in some microorganism, as from any of the acute infectious diseases. This was later demonstrated to be a fact, as the organisms were found in the vegetations on the valves. The difference between the simple and the ulcerative or malignant form is chiefly one of degree of infection, or rather involvement, of the heart. The different microorganisms were soon demonstrated by numerous observers. The pyogenic organisms, streptococcus and staphylococcus aureus and albus were most often found to be the cause. Next in frequency the



pneumococcus, the influenza bacillus, the colon bacillus, the tubercle bacillus, and finally, comparatively recently, the ubiquitous gonococcus have been found in the active rôle of the cause of endocarditis. Thus endocarditis may be found as the terminal or intercurrent affection of such infections as erysipelas, carbuncles or pus anywhere in the body, either of staphylococcic or streptococcic origin, or following acute infectious diseases. The most common cause of simple endocarditis—rheumatism—is now numbered among the infectious diseases, or rather diseases of microbic origin.

The first case of gonorrheal endocarditis—so proven—Whittaker says was reported by Leyden in 1893. It is only within the last ten or fifteen years that gonorrhea has been looked upon as the cause of endocarditis, and even now the number of cases reported is comparatively small. Because of the inability to find the gonococci present, either in the blood or on the vegetations of the valves, it is held by some that the infection is a mixed one and the cardiac lesions are due to the pyogenic organisms.

While it is undoubtedly true that the infection is sometimes a mixed one, and that the pyogenic organisms only are found in some cases, I think most often the real cause for not finding the gonococci lies in the inability to make the organism grow on the media as commonly used in the laboratory for other organisms. Johnston and Harris, in an article in the Johns Hopkins Hospital Bulletin for October, 1902, on this subject, give as their conclusions, in regard to the cultivation, etc., of the gonococcus, the following: "(1) To cultivate the gonococcus from blood during life it is neither necessary to use a large amount of blood nor to greatly dilute the blood, nor to employ any specially prepared media. (2) It is more advantageous to mix the blood with melted agar and plate the same than to use fluid media where oxygen supply is more restricted. (3) That the time selected for making the culture taken in relationship with the course of the disease may be a factor of sufficient importance to be taken into consideration. (4) Compared with its action upon the typhoid bacillus and pneumococcus the bactericidal power of the blood seemingly has little effect in retarding growth of the gonococcus."

C. J. Habhegger, in an article in the *Philadelphia Medical Journal* of May 30, 1903, says of the difficulty of cultivating the organism: "The gonococcus grows very slowly, requires a special medium and is readily killed by slight changes of temperature, while the microbes ordinarily responsible for septic endocarditis are not difficult of cultivation on blood serum, agar-agar or gelatin. The method of making cultures is of practical importance and is performed as follows: Blood is drawn from the median bacillic vein by means of an aspirating syringe under aseptic conditions and mixed with twice as much agar-agar and then plated."

In his case the fact of negative cultures made from the blood during life, and from the vegetations and the organs of the body at autopsy, rather substantiates the diagnosis of gonorrheal involvement than otherwise, because of the known difficulty in cultivating the organism.

Babcock thinks that the virulence of the infecting organism usually determines the character of the cardiac lesion: that is, as to whether it is simple or ulcerative endocarditis.

One English writer, Fürth (*Edinburgh Medical Journal*, xviii, 1905, 33-38) speaks of a "gonorrheal" and a "gonococcal" endocarditis, the first following the inflammation of gonorrhea by reason of a point of entrance being made for streptococcic or staphylococcic invasion. "Gonococcal" is that form where the gonococci can be found in the blood during life, or tissues after death, and in which they or their products are the active cause of the endo-

*Paper read before the Medical Society of the District of Columbia.

carditis. This division seems to me unnecessary, as I think that with more exact culture methods the gonococci may be cultivated in many of the cases where now they are not found; although I do not mean to say that there cannot exist, as does in other microbic conditions, a mixed infection.

A hurried résumé of the cases reported by different authors shows that almost all the cases where *Staphylococcus pyogenes* was found in the blood during life proved fatal. Nearly all authorities who have reported cases in which bacteriological examination was made of the blood during life, have occasionally obtained negative results. Glynn of England (*Lancet*, April 11, 1903) reports negative results in several cases even though he used several cubic centimeters of blood. Habhegger reports the same; Thayer the same. Habhegger holds that some cases are due to the toxins of the gonococcus. This theory is held also as regards gonorrheal rheumatism.

The symptoms of the disease are so well marked that I will not give any extensive outline of them. The case that I will report later shows most of the typical symptoms of the disease, beginning with the infection of gonorrhea. A great many of the cases do not present symptoms of the general infection until the discharge from the urethra has stopped; sometimes when it has been checked very rapidly in the "quick cures" so promiscuously advertised in the papers.

The signs of a general septicemia exist as in any well marked case of septicemia. The heart sounds are of interest but not differing particularly in gonorrheal septicemia from any other septicemia in which the valves or endocardium of the heart are involved. One peculiarity in these cases is, as stated by several authors, that the heart sounds are not amenable to any ruling; that is, they change very frequently in character and cannot be gauged by the rules usually obtaining in other cardiac cases. In some of Thayer's cases, recently reported, the sounds during life were such as to cause the diagnosis of mitral stenosis. At autopsy no marked involvement of the mitral valves was found. Then again, the valves and endocardium of the heart may be involved to a marked degree without any physical signs on auscultation being heard. A case in point is one coming under my observation recently which at autopsy showed marked vegetations on the mitral valves, but during life presented no evidences upon auscultation or otherwise of any pathological lesion.

In the more severe cases of infection the septic temperature is very marked. There are wide excursions of temperature together with marked rigors; then again in milder cases, as in one reported by Thayer recently, the temperature runs a course very much like a mild typhoid fever. In fact, it was some time before Thayer could make a diagnosis between typhoid fever and gonorrheal septicemia. These milder cases, which often get well, are the ones which are more difficult to diagnose. The symptoms appear mild and the course of the fever is such as to lead one to believe it to be of typhoidal or malarial origin. One of the characteristic conditions seen in the severer cases is the *very* septic appearance of the patient. In these cases, as in other cases of infective endocarditis where there are vegetations on the heart valves, we may expect emboli and infarcts in the different organs of the body.

The diagnosis rests primarily upon the existence of a gonorrhea to which alone can be traced the source of an infection severe enough for the symptoms present. The mere fact of the organisms not being found either in the blood during life, or in the tissues at autopsy, does not to my mind invalidate the diagnosis of gonorrheal septicemia, for the reasons stated earlier.

The cases presenting severer symptoms of septicemia do not, as a rule, present marked difficulties of diagnosis. But the milder ones are the ones which are most often overlooked and diagnosed as some other infection. The prognosis, in these cases, depends, as in other cases of infective endocarditis, to a great degree upon the character of the infection. The milder cases *may* get well; the severer cases rarely do. If the case has a mixed infection with the staphylococcus present, a fatal prognosis is almost certain.

The treatment of these cases, as of all cases of ulcerative endocarditis, is very unsatisfactory. In the majority we can only use palliative measures and keep up the strength of the patient. In those cases where there is a mixed infection of streptococcus, antistreptococcic serum may be used. This has been used in some cases of malignant endocarditis where streptococci were shown to be present in the blood stream during life, with a few cases of recovery. If, as is held by some, the cases are pure streptococcic infection, which infection has gained entrance through the lesion in the urethra caused by the gonorrheal inflammation, and the gonococci or their toxins are not active agents in the infected blood or system, then the use of antistreptococcic serum, if it is any good at all, would be indicated. There have been some cases of infections, both by streptococci and staphylococci which have been exceedingly benefited by antistreptococcic and antistaphylococcic serum. Some cases have been reported cured.

I am indebted to Dr. T. Morris Murray for the following case as it came under his service at the Emergency Hospital:

S. Z., male, eighteen years old, Italian; laborer; family history negative; patient not able to speak much English, so history rather difficult to elicit. There is a history of no other diseases except that of gonorrhea recently.

Contracted gonorrhea February 15; discharge from urethra stopped March 10, after using medicine from drug store. Arthritic pains in both ankles followed. Has had fever for a month, and has had daily chills and fever for fifteen days this month. He worked until April 10. Came into Emergency Hospital on April 22. On April 23 the following physical examination was made:

On inspection a red spot, about the size of a quarter, was seen on the outer upper side of the left foot and also on the outer side of the last phalanx of the left third finger. Both spots were tender. Patient was pale, anemic looking, but did not present a markedly septic appearance. The apex beat was seen outside of and half an inch below the nipple. It was diffusible and carried up over the precordial region toward the base of the heart. Pulsation marked in both carotids.

The pulse is obliterated from the junction of the left axillary and brachial arteries, at which point there is tenderness and the artery can be felt hard under the finger. The arm was cold, pallid, and numb when admitted to Hospital yesterday. At present it is cooler than the right, but the color is normal and it does not feel so numb. Pulse is rapid, without force. With the impulse at the apex of the heart is a slight thrill on systole.

Two inches to the left of the sternum at the second intercostal space a high-pitched sound, almost typical cracked-pot in character, is heard on percus-

sion. The heart extends about one inch to the left, of normal dullness.

Breath sounds are increased over the entire left lung, more especially over the upper lobe. There is a loud sawing murmur with the systole at the apex of the heart which is transmitted three inches in all directions. The second sound is not clear. Over the pulmonary valve area there is a duller first sound; both sounds at the base are dull and booming. The heart murmur is heard posteriorly and the murmur is also heard in the axillary and brachial arteries of the right arm and at the outer end of the axillary in the left. No urethral discharge.

He complains of pain over the precordial region and some slight articular pain in the ankles. No other pains. An icebag applied to the precordia relieved the pain.

April 24: There is pain in the calf of the left leg; no pulsation is felt in the left tibial artery at the inner malleolus, but at the popliteal space. The red spot on the right foot is not so marked to-day, but still tender, and the same with the spot on the third finger of the left hand.

April 27: Leucocyte count showed 11,532.

April 29: Murmur heard with the systole at the apex is not so loud or rasping to-day.

April 30: At irregular intervals chills, with large excursions of temperature, and the pulse varies between 84 and 138.

May 1: Blood examined for malarial parasites and stained, but none found.

May 5: A few small hemorrhagic spots are noted around the neck and the upper part of the chest.

May 7: Has numerous pustules, about the size of a split pea, on the right side of back of the thorax. These appear pustular from the beginning and have very slightly reddened bases. Temperature extremely irregular, chills and sweats frequent; the patient sleeps a great part of the day and night. Pulse has returned in the left radial, but is very small and easily obliterated by pressure. The vessel does not seem to be full; evidently a collateral circulation has taken place through a small artery.

May 8: Pus from the pustules on the back stained and examined microscopically and showed many cocci and a few diplococci which retained the Gram stain.

The patient vomited several times daily during the latter part of his illness, and often refused nourishment and medicine. He did not complain much of pain after the icebag was applied to the heart, and insisted upon keeping it on his chest until a few days before his death. The diet was chiefly milk at first and later a more sustaining diet in the form of eggs, broths, etc. As the illness progressed he became paler and had a marked septic appearance, with an increasing number and severity of chills. The chills sometimes lasted for several hours. On April 30 a chill began at 7 p. m. and lasted until 10:30. On May 1 a chill began at 12 noon, and lasted until 3 p. m. On May 2 he had some bleeding from the nose, and the same condition was present on May 4 and May 6, and during this time he vomited frequently and had high ranges of temperature with chills and sweats. On May 7 his feet were slightly swollen; septic condition continued, becoming more severe as the disease progressed.

The uranalyses show the following: On April 23 nothing abnormal was found. On April 26, trace of albumin was found, with numerous hyalin and fine and coarse granular casts. On May 1, albumin was still present and numerous red cells and hyalin and fine and coarse granular casts. The same condition on May 5; also the presence of numerous leucocytes and blood casts.

About the 1st of May Dr. James Carroll of the Army was asked to take a blood culture from the patient. He sent his men over from the laboratory of the Army Medical Museum, and with aseptic precaution 10 c.c. of blood was drawn from the median basillic vein of the right arm, distributed over twelve agar plates, and taken to the Army Medical Museum, from which Dr. Carroll reports there were no growths of any kind.

The patient died on May 11, and the following autopsy was done twelve hours after death: Body fairly well nourished; apparent weight 140 pounds.

A few small petechial spots on left chest and around base of neck. Broken down pustules on back. Body white and anemic. Feet slightly edematous. Rigor mortis present. Right pleural cavity contained about 500 c.c. fluid; no adhesions. Lower edge of lower lobe of right lung had small fibrous flake on it, evidently a slight adhesion. Left lung normal. Crepitated. No adhesions. Right lung same. Heart large, soft, and flabby. Pericardial sac contained about 100 c.c. of a greenish yellow fluid. Wall of left ventricle very soft and friable. There was a large, white ante-mortem clot in left ventricle. Large, soft, friable vegetations covering mitral leaflets. Left auricle walls thin and flabby. Ante-mortem clot filling right auriculoventricular ostium. Tricuspid valves showed slight thickening and contained a slight vegetation or very small thickened mass. Right heart very pale. Aortic valve normal. Wall of aorta pale and thin. Pulmonary valve normal.

Peritoneal cavity and intestines pale; greater omentum very dark. Intestines and stomach full of gas. About eight inches jejunum and its mesentery dark and injected fan-shaped. Peritoneal cavity contained about 200 c.c. of fluid.

Spleen was adherent on posterior edge; was about three times its normal size, dark purplish in color. About the middle of the outer surface there was an irregular shaped spot (infarct) about the size of a silver dollar. Red area around border and darker in the center; adhesions formed over center; anterior surface near the notch had a similar smaller spot; there were also one on the posterior edge, one on the upper end, and one on the anterior border about the middle; all hard and apparently necrotic. On section, the organ was very soft and had a large white infarct; pyramidal shaped at first spot mentioned above.

Left kidney was slightly enlarged and pale, and was very pale on section. Capsule stripped easily. Right kidney slightly enlarged and pale. Anterior lower surface had infarct like spleen. There was also a small one on the upper posterior surface. On section, darker than the left. Pyramids very well marked and had a well marked infarct.

Liver was normal in size and on section was soft and friable.

Bladder was small and the walls were hard and thickened.

Cultures were taken at autopsy from the pericardial fluid, left ventricle, vegetations on mitral valve, and the spleen and were sent to Dr. Carroll. He reported that from one of the cultures made at the autopsy the *Staphylococcus pyogenes aureus* was grown, but he did not know from which one of the organs the culture was taken, as the culture tubes were mixed up and the labels lost.

Sections of the spleen and kidney were also sent to Dr. Carroll, but they were mislaid, and no report could be gotten on them.

VESSEL ANASTOMOSIS BY MEANS OF RUBBER TUBING.

By WILBUR WARD, M.D.,

NEW YORK.

FROM THE DEPARTMENT OF CLINICAL PATHOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY.

In the course of a series of laboratory experiments dealing with the subject of vessel anastomosis and transplantations, it was thought that if it were possible to transplant, with functional success, formalized or otherwise devitalized segments, it should be possible to obtain a successful result with inorganic segments. Rubber tubing was therefore implanted in the aortas of cats. In the first experiment, the aorta was isolated and laid bare just below the renal arteries, and a segment of tubing, two cm. long, was inserted in continuity by the Carrel method. The rubber was of the pure black gum variety, and the diameter of the lumen was the same as the outside diameter of the aorta after the latter had undergone the usual contraction incident to its exposure and section; for it has been found that in transplanting devitalized segments it is necessary, or at least advisable, to have the piece transplanted of larger diameter than the vessel of the host. The tubing was filled with vaselin, the excess of which was squeezed out just prior to tying the last suture. No difficulty was experienced in suturing the rubber to the vessel, and the sutures did not tend to tear out as it was feared would be the case. There was no hemorrhage from the suture lines when the temporary ligatures were released, and the aorta below the anastomosis, and the femorals pulsated normally. The abdominal incision was then quickly closed. There was little shock; and the next day the animal, if allowed, would walk about normally, and was in excellent general condition. The pulsations of the femorals could be felt and the circulation in the extremities was good. On the fourth day, the cat showed marked epigastric distention, vomited persistently, and soon died. At autopsy a volvulus of the upper part of the small intestine with beginning peritonitis was found. The aorta and implanted segment were removed and hardened in formalin. There was a peripheral thrombus beginning at the suture line at either end and extending the entire length of the rubber tube, but the canalization in the center was large enough to pass sufficient blood for the nourishment of the hind extremities.

A second cat was then operated upon in exactly the same way. The tubing was inserted into the aorta just below the renal arteries, and the suture was as satisfactory as before. There was no hemorrhage and the circulation below the anastomosis was perfect at the completion of the operation. The cat went on to an uneventful recovery, and a week later was in better general condition than when received into the laboratory. After the second day she appeared perfectly normal in all respects save for the abdominal wound, which healed readily. After three weeks the cat was killed and an immediate autopsy was performed. The transplanted segment of rubber tubing was completely thrombosed, and the circulation in the hind extremities had been maintained by an effective anastomosis between branches of the adrenolumbar and iliolumbar arteries, branches of the aorta given off just above and below the site of implantation. There was a thick zone of dense connective tissue encircling the rubber and adjacent portions of the aorta.

As the pulsations in the femorals could at all times be felt, it is apparent that the occlusion of the tubing had taken place so slowly that the animal had had time to establish a sufficient collateral circulation, for ligation of the aorta in either the cat or the dog is soon followed by paralysis of the hind extremities and fairly rapid death.

It has been repeatedly shown that the circulation can be maintained by the implantation of segments of either artery or vein from either the same or different species of animal, but it is not difficult to imagine a surgical situation where the immediate restoration of the circulation is imperative and where the necessary living tissue is not at hand and cannot be immediately obtained. Under these circumstances rubber tubing, in some cases at least, might be used to maintain the circulation temporarily.

Similar experiments have been made by Abbe, who in 1894 inserted a piece of glass tubing into the aorta of a cat. While the lumen of the tube was gradually occluded, the process was slow enough to allow of a sufficient collateral circulation to be established. Rubber, however, has many advantages over glass. It can be readily inserted by the suture method and the anastomosis is not appreciably more difficult than the similar performance with living tissues. Within certain limits, one size of tubing can be used for vessels varying considerably in size, while with the glass many cannulæ of various sizes must be kept on hand and the proper one selected for the anastomosis in question. With the suture method, which can be used with the rubber, the danger of immediate thrombosis is not great, while it is the rule with glass, the introduction of which into the vessel is a matter of complicated technique. Finally, the effect of trauma on glass can readily be disastrous, while no such effect need be apprehended when rubber is used.

My thanks are due to Dr. Paul W. Kimball for his kind assistance in the operative procedures.

The Direction of Abdominal Incisions.—A. E. Maylard offers the following conclusions: (1) When time is not of paramount importance, more permanently secure cicatrices result from transverse than vertical incisions, whether median or extramedian. (2) Transverse incisions afford more room for the treatment of pelvic diseases, and are also better for exploratory purposes. (3) Vertical incisions involve the division of fewer blood vessels, and the apertures can be closed by a single series of through-and-through interrupted sutures. For these reasons, therefore, they can be executed much more expeditiously than the transverse, and should be employed in all cases where time is a serious consideration. (4) In dividing the sheath of the rectus, the chief end to be aimed at is to carry the incision as much as possible in the line of the fibers of the aponeurosis. Thus, in the upper part of the abdomen for, say, 2 inches from the xiphoid, the incisions should course obliquely from above downwards and outwards. In the lower part of the abdomen, for, say, 2 inches from the symphysis pubis, the incisions should be carried obliquely upwards and outwards. In the central part of the abdomen—that is, between those parts just delineated—the incisions should be transverse. (5) If sufficient room can be obtained by separation of the recti muscles after division of their sheaths, the fibers of these muscles should not be cut; and when division is necessary it should be carried obliquely, so as, if possible, to leave some of the outer fibers undivided. (6) Serial suturing should be employed, and particular attention should be given to the accurate coaptation of the edges of the divided aponeurosis. (7) No operation should be performed, if the exigencies of the case do not otherwise demand it, when the patient has a cough which it is possible to cure or alleviate. (8) Four weeks should be allowed, at least, after the operation for rest in the dorsal or semirecumbent position, and two months more before any undue strain is exercised on the wound. In wounds which become septic, and therefore heal by granulation, six weeks to two months should be allowed for complete rest in the dorsal position.—*British Medical Journal.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, October 17, 1908.

ASEPSIS IN CHILDBIRTH.

IT is only a little over sixty years ago that Oliver Wendell Holmes laid the foundation of a new era in our knowledge of puerperal sepsis by insisting upon the contagious character of puerperal fever, and Ignaz Semmelweiss wrought a great change in the mortality of a maternity ward in Vienna by the simple expedient of having the students wash their hands in chlorine water before examining parturient women. The new doctrine taught by Holmes was fought by his contemporaries in America, and Semmelweiss was so derided and ridiculed by the physicians in Vienna that the disappointment drove him to an insane asylum. Pasteur and Lister completed the work begun by these two men by discovering the bacterial origin of septic infection and its prevention by antiseptic and aseptic methods; and then the frightful mortality of the puerperal bed became forever a thing of the past.

The great change that has taken place in this department of medical activity is well illustrated by the results attained by Hofmeier in the University Maternal Clinic at Würzburg. In the *Münchener medizinische Wochenschrift* for September 15, 1908, Hofmeier tells the story of the last ten thousand patients at the clinic. Of them only nine died of puerperal sepsis, six deaths having taken place among the first three thousand deliveries of several years ago; in the last seven thousand deliveries only three cases of sepsis occurred, and all three could be traced to infection outside of the clinic. These seven thousand deliveries without a single case of infection in the clinic form a remarkable showing when it is remembered that each parturient woman was examined by from three to nine medical students or candidates for the midwifery licenses. Moreover, the clinic directed by Hofmeier is not a palatial institution with all modern conveniences, which many American physicians look upon almost as *sine qua non* of successful medical management and treatment The Würzburg institution is much cramped for space, and is one of the least well furnished maternity clinics in Europe. The simplicity of the aseptic technique, too, is worthy of being mentioned. No very elaborate sequence is used in the disinfection of hands, careful and prolonged cleansing with soap, followed by bichloride having been found amply sufficient. The addition of alcohol to this cleansing was not followed by any better results, while rubber gloves are looked upon by Hofmeier as entirely unnecessary in the general run of cases, however indispensable they may be under special circumstances. He considers that the routine use of rubber gloves leads to a quite unjustifiable expense, for equal results may be obtained by the thorough disinfection of hands, and especially by a most careful cleansing of the parturient woman.

Hofmeier claims to have attained the ideal of a maternity clinic. His institution serves as a great teaching center for the medical students of the university and for aspiring midwives, and yet this instruction has been rendered completely safe for the patients that serve as the objective material for teaching. The results attained by him once more dispose of the objections to the general admission of students to the hospital wards such as are frequently made by well-meaining but poorly informed philanthropists. Just as the presence of students in the general wards of a hospital spurs the attending and resident physicians to greater accuracy in diagnosis and more careful treatment of disease, so the care required in maternity institutions to prevent any possible infection from repeated examinations of parturient patients throws increased safeguards about the women who trust themselves in childbirth to public institutions.

PARSIMONY IN NUTRITION.

A MARKED and in some respects curious change has taken place in the last few years in our dietetic notions. In the last century overeating or rather redundancy in nutrition was recommended, but now the pendulum has swung in quite the opposite direction. Physiologists and physicians of high authority are preaching this new doctrine and advising not merely simplicity of diet, but an abstemiousness carried to a degree that would have been regarded formerly as absolutely dangerous. The trend of public opinion and perhaps even of medical opinion is assuredly towards a reduced dietary. The new doctrine is, however, not accepted without a protest. Sir James Crichton-Browne in an address delivered a short time ago took parsimony in diet for his text and made an eloquent plea against the present day teaching. The experiments of Voit of Munich and Atwater of this country in connection with diet were referred to. Atwater's standard for a man doing moderate work places the proteid requirement at 125 grams with sufficient fat and carbohydrate to equal 3,500 calories. The Voit and Atwater standards have up to recent times been regarded as representing the minimum of what is necessary for the maintenance of health and strength, but the new dietetic philosophy holds that these standards are false, and that the quantities of foodstuffs allowed by them are far larger than the requirements of the body actually demand. As to proteids in particular we are now informed that we have been partaking of double or treble the amount that is necessary.

Sir James Crichton-Browne contended that this theory has received far more attention from scientists and physiologists than it deserves, and he proceeded to discuss Professor Chittenden's views on nutrition. While giving all credit to Chittenden for his brilliant and painstaking investigations on the subject, the speaker held that his views conflict with the orthodox physiological faith, as Chittenden's standard of proteid food is not only one-half

lower than that of Voit, but is still further below the common practice of the enormous majority of mankind in Europe and America. "If he is right," said the speaker, "then all the world up to this time, with the exception, perhaps, of a few supposed faddists, has been wrong. Gluttony has somehow become universal. It is Chittenden contra mundum."

The argument is advanced that it is not on *a priori* physiological data, nor yet on laboratory experiments, that the science of dietetics is to be based, but on common observation and on the hereditary customs and habits of mankind. It is pointed out that the lower animals select with unerring precision, as long as they are in a natural environment, from the materials around them those best fitted to their wants, and they do this by instinctive discernment inherited from a long line of naturally selected ancestors, while they are checked in their consumption by a sense of repletion of coeval origin. It may be unhesitatingly inferred that the articles they choose are, of all nutrient material accessible to them, those best adapted to the special needs of their economy, and that their consumption of them is proportioned to their needs for the time being. But man is, as regards his bodily functions, subject to the same laws as those which govern the lower animals, and it cannot be doubted that in the formation of his dietetic habits he has been guided by the same kind of influences which have been operative throughout the animal creation in the choice and consumption of food. The dietetic habits of civilized races are tardily ingrained instincts, which have been differentiated and elaborated as man has advanced in civilization. Sir James Crichton-Browne quoted, in support of his opinions, the manner of food eaten by the greatest ancient and modern nations and finally concluded that despite the result of recent dietetic physiological experiments the food generally consumed by the leading people of the earth is best adapted both in quantity and quality to their physical and mental requirements.

Undoubtedly many people eat and drink too much, and it is quite certain that a person who is engaged in sedentary employment needs far less meat than one who lives in the open air and who takes much exercise or who performs hard manual labor. But to assert dogmatically, although experiments would seem to show that the view is correct, that proteid food is almost unnecessary, is possibly carrying the argument too far. Experience is in a way more valuable than experiment, and experience has taught us that the most successful nations have done remarkably well on a proteid diet. It might be said that on a nonproteid diet they would have done better, but there can be no proof of this.

OLD AND NEW CONCEPTIONS OF HYSTERIA.

Few observers who have had any great amount of experience with hysteria have believed that its cause lay in any obscure pathological entity. The weight of evidence has been against such assumption from the beginning, and the world's greatest alienists are fast adopting the view that hysteria means simply disordered function without organic change. That is the primary or essential type of hysteria; but there is a secondary type of nervous manifestation, usually classed as hysteria but improperly so, which comes on after street-car or railway accidents, falls, frights, etc. The functional changes are often associated with some circulatory disturbance, such as anemia or hyperemia of an organ, appearing spasmodically upon sudden fright, or as a result of worry or excessive nervous stimulation. Globus hystericus so-called is sometimes due to increased congestion of the blood-vessels of the esophagus, and is usually most pronounced after the ingestion of condiments or alcoholic beverages. Spasm of the cardiac end of the stomach is not infrequent, as is evidenced by the difficulty one often has in passing the stomach tube. In some cases there is probably a pyloric spasm as well, for the stomach contents may be brought up undigested several hours after being swallowed.

The well-known contraction of the field of vision is possibly due to an imperfect blood supply brought about by a diminution in the size of the terminal arterioles. The central artery of the retina may function imperfectly, yet be not completely cut off; hence central vision is maintained. Moreover, relief of gastric and esophageal irritation has been brought about by drugs such as fluid extract of ergot; and cardiac and nerve-stimulating drugs sometimes serve a useful purpose in combating other troublesome symptoms dependent on a disordered nervous and arterial system.

While still inconclusive, the work done along this line at the recent French and international neurological congresses has been illuminated by a symposium of the Paris Neurological Society. The objective facts presented there confirm the assumption that the alleged stigmata of hysteria have no pathognomonic value and are merely the results of suggestion generally of medical origin (*Presse Médicale*, July 4, 1908); also that modifications of tendon and pupil reflexes do not properly belong to the symptomatology of hysteria. Illustrative of this view is the opinion of Babinski who has reconstructed from the ruins of former conceptions of hysteria a new definition which implies that there is a special psychic state manifesting itself in disturbances distinguished by the fact that it is possible to reproduce them by suggestion in certain persons and to cause them to disappear in certain others by the power of persuasion. Babinski thinks that so-called hysterical fevers, hemorrhages, etc., should be excluded from the category of hysterical manifestation inasmuch as such origin has been unproven.

Evidently, therefore, the tide of medical feeling regarding this mysterious disease is turning back again to the old ways when these unfortunate patients received scant courtesy at the hands of physicians. The task should not, however, be given up so readily, since the study of the disease is in itself a most absorbing one, and the literature coming from the pens of distinguished observers, such as Janet, is so thoroughly replete with human interest. The camps of the alienists are likely to remain divided for some time to come, especially as to etiology and treatment. In the meantime those practitioners who are necessarily esoteric may continue to hold their own opinions as to the nature of hysteria and treat it after their own fashion.

Antimeningitis Serum.

The discovery of an antimeningitis serum by Drs. Flexner and Jobling of the Rockefeller Institute for Medical Research, and the favorable results obtained in the first few cases treated with it, have been widely heralded by both the medical and the general press, especially as its introduction in the therapy of meningitis was followed by a new instance of munificence on the part of the founder of the institute. The actual results following the use of the serum, however, have been very hard to judge, the nature of the disease furnishing individual physicians but limited material from which conclusions could be drawn. The discoverers of the serum have supplied it to physicians on the express condition that full reports of the cases in which it was used should be sent them, and in the *Journal of Medical Research* for September 5, 1908, they analyze the reports of several hundred cases so treated. These cases occurred in different parts of the United States, Canada, and Great Britain, either as sporadic instances of the disease or during epidemics of varied severity and extent. The mortality of the disease in both epidemic and sporadic form was about seventy-five per cent., though it was not uniform everywhere, severe outbreaks being reported in some localities while others seemed to have suffered from infection of a rather low virulence. Everywhere, however, the use of the serum was followed by diminution of deaths from the disease. Thus in Akron, Ohio, there were nine deaths out of the first ten cases, a mortality of ninety per cent.; serum was employed in the next twelve cases, and of these there were nine recoveries, a mortality of twenty-five per cent.; in Scotland and Ireland the mortality in the cases treated without serum ranged between seventy and ninety per cent.; the cases treated with the serum showed mortalities varying from 26.7 to 44.5 per cent., even when all fulminant cases or those moribund at the time of the injection of serum were included. Of the total 393 cases considered in the analysis there were seventy-five per cent. of recoveries. Children under one year gave fifty per cent. mortality, while previous to the use of the serum Holt reported that of twenty cases under one year in the hospital wards not one recovered, and Koplik states that of twenty-seven such cases observed by him twenty-three either died or were discharged unimproved. In addition to these figures giving the general mortality of the disease under the application of the serum, the authors present much evidence that testifies to the promptness of recovery and the greater frequency with which complete cures were obtained when such sequelæ as deafness, blindness, and mental impairment are considered. In general, the success attending the use of the serum fully justifies the conclusion of the authors that "antimeningitis serum, when used by the subdural method of injection in suitable doses, and at proper intervals, is capable of reducing the period of illness, of preventing in large measure the chronic lesions and types of the infection, of bringing about complete restoration to health in all but a very small number of the recovered, thus lessening the serious, deforming, and permanent consequences of meningitis, and of greatly diminishing the fatalities due to the disease."

Complement Fixation in Malignant Disease.

Wassermann has claimed that substances are formed in the body of a syphilitic which react in a certain specific way with extracts of syphilitic tissues; this reaction is accompanied by the "fixation of complement" and a consequent inhibition of hemolysis in a mixture of substances in which the hemolytic agent cannot act because of such fixation of complement by the specific syphilitic bodies. Drs. Simon and Thomas have applied this reaction to the study of malignant disease, in which either a specific parasite could be supposed to give rise to substances capable of fixing complement or the cancer cell itself could be looked upon as such a parasite. Although no strikingly uniform results were obtained, yet the data given by the authors in the *Journal of Experimental Medicine*, Vol. X., No. 5, are of interest, as is everything that may throw light upon the mystery of malignant disease. In fifty non-malignant cases used for control, fixation of complement, as shown by the inhibition of hemolysis occurred but twice, and in one of these cases tertiary syphilis was demonstrated. In malignant disease, on the other hand, fixation occurred in sixty-five per cent. of the cases. The investigations were carried out with extracts of mammary cancers. The authors very properly refuse to theorize on the basis of their observations, both because not enough cases have been examined and because the very nature of the reaction has been questioned in the case of syphilis. It is quite questionable, for instance, whether the reaction is due to the binding of the complement by the hypothetic specific bodies of syphilis, it having been shown that it may take place with substances other than the extracts of syphilitic organs.

An Early Symptom of Perforative Appendicitis.

Inflammation of the appendix may exist in any degree from that of slight catarrh to gangrene, with or without perforation. In the early stages of the disease most surgeons are agreed that the patient should be kept absolutely at rest and be given a restricted fluid diet, an icebag being placed over the seat of pain. It is also generally agreed that perforative appendicitis demands immediate operation. In any given case, however, it is often impossible to make an early diagnosis of perforation, and the patient is not operated upon until symptoms of periappendicular inflammation or diffuse peritonitis have set in. In the *Presse Médicale* of June 3, 1908, Pierre Delbet draws attention to a single symptom by means of which he claims to be able to make an early diagnosis of perforation of the appendix. If the symptoms of a patient with signs of a beginning appendicitis are relieved by ice, rest, and fluid diet, and he is suddenly attacked with pain during the above treatment, Delbet claims the appendix is perforated and advises immediate operation, even if the patient's general condition is good. He cites numerous cases in which his early diagnosis was substantiated by operation, and urges the wisdom of operating at once when, without interruption of the above treatment, pain suddenly becomes worse after the symptoms had first been improved by the treatment.

Leucocytes in Basedow's Disease.

The diagnosis in goiter is usually possible from the physical examination without the aid of the history, and is difficult only in rare cases. Inspection, palpation, and laryngoscopic examination give the necessary data. We should, however, not be satisfied with the diagnosis of goiter alone, but should endeavor to discover which variety we are dealing

with. Exophthalmos, tachycardia, and trembling point to Basedow's disease, but one or all three of these symptoms may at times be absent. It is then that the kind of goiter is more difficult to diagnose. From a prognostic point of view a correct diagnosis is of great importance, especially if surgical treatment is decided upon, and any additional differential sign will therefore be of great value. At the thirty-seventh meeting of the German Surgical Society held in Berlin in April of the present year, Kocher of Bern drew attention to the white blood cells in patients with Basedow's disease. He examined the blood in over one hundred patients and found the number of white blood cells to be under four thousand per cubic millimeter. The percentage of multinuclear neutrophiles was greatly diminished, while that of the lymphocytes was increased. After partial extirpation of the thyroid normal blood conditions returned. Kocher furthermore found that these blood changes occurred early in the disease before the other symptoms became pronounced and were most marked in the severe cases of Basedow's disease.

News of the Week.

Harvey Society Lectures.—A very interesting program is announced by the Harvey Society for its course of lectures during the winter of 1908-09. The course will be as follows: October 24, "Intestinal Infection and Immunity in Tuberculosis," by Prof. A. Calmette, Director of the Pasteur Institute of Lille, France; November 7, "Fever," by Prof. W. G. MacCallum, of Johns Hopkins University; November 21, "Metabolism in Diabetes," by Prof. Graham Lusk, of the University and Bellevue Medical College; November 28, "Therapeutics of Diabetes," by Dr. Wilhelm Falta, of the University of Vienna; December 5, "Anaphylaxis," by Dr. M. J. Rosenau and Dr. John F. Anderson, of the United States Public Health and Marine Hospital Service; December 19, "Osmosis," by Prof. A. B. Macallum, of the University of Toronto; January 9, "The Relation of the Liver to the Metabolism of Fat," by Prof. J. B. Leathes, of the Lister Institute of Preventive Medicine, London; February 6, "Some Problems in Immunity and the Treatment of Infectious Diseases," by Prof. Philip Hanson Hiss, of Columbia University; March 6, "Heredity in Man," by Dr. C. B. Davenport, of the Station for Experimental Evolution, Cold Spring Harbor, N. Y. The lectures are given under the patronage of the New York Academy of Medicine, on Saturday evenings at 8:30, at the Academy of Medicine, 17 West Forty-third Street. They are for the benefit of the medical profession, and all who are interested are cordially invited to attend. Prof James Ewing, of Cornell University Medical College, is president of the society, and Prof. Francis Carter Wood, of the College of Physicians and Surgeons, secretary.

Philadelphia Founders' Week: Medical Day.—During the celebration of the 225th anniversary of the founding of Philadelphia by William Penn, Thursday, October 8, was devoted to Medical Day. In the morning a meeting was held at the Walnut Street Theater, where a report on behalf of the Committee on Scientific Institutions, Colleges, and Hospitals was made by Dr. John V. Shoemaker. Drs. Chas. K. Mills and Frederick P. Henry presented the report of the committee on the Volume of Scientific Institutions, Colleges, and Hospitals. Dr. Joseph P. Remington submitted the report of the Committee on Historical Exhibit. Dr. L. Webster Fox made a report on behalf of the committee on Medical Day. Dr. George A. Peirsol delivered a scholarly address on the Medical Colleges and Allied Institutions of Philadelphia. Dr. S. Solis-Cohen spoke eloquently of Famous Physicians of Philadelphia. Dr. J. M. Anders delivered an interesting address on the Development of Practical Medicine in Philadelphia. In the afternoon a reunion of former and present members of the visiting and resident staffs of the Philadelphia Hospital was held in this institution. An address of welcome on behalf of the Mayor and the city was delivered by Dr. Joseph Neff, Director of Public Health and Charities. Dr. Roland G. Curtin spoke of the early history of the Philadelphia Hospital, Dr. Chas. K. Mills of Some Blockley Doctors and Some Personal Experiences, and Dr. Alfred Stengel of Blockley and Clinical Teaching. In the evening a smoker was held at the Bellevue-Stratford, and among other things brief, addresses were delivered by Governor Stuart and Mayor Reyburn.

Anti-Noise Bills.—Four ordinances designed to restrict street noises in New York, which were recently introduced before the Board of Aldermen, will be given a public hearing on October 19. The ordinances are backed by the Health Commissioner and the Society for the Suppression of Unnecessary Noise. They provide for fining railway companies operating flat-wheeled cars, or cars with loose trucks or chains, or maintaining broken or loose rails or switches, etc., the fine for each offense not to exceed $500. Peddlers are forbidden to make any noise whatever for the purpose of calling attention to their wares, and except at the intersection of streets, the blowing of horns or sounding of bells on any vehicle is forbidden.

School for Deaf Mutes.—New York City has just opened the first public school for deaf mutes in America, believing that official steps should be taken to improve the condition of hundreds of deaf mutes who are growing up as illiterates and dependents. The work is, of course, under the direction of the Board of Education, and the Board has also received from the Institution for Improving the Condition of Deaf Mutes an offer of its entire plant, building, teachers, and pupils, to be incorporated into the public school system. Established forty-four years ago, this institution has carried on, in a semi-public way, a work of great value in training deaf mute children to become self-supporting. There is also a training school for teachers connected with it, which solves the difficult problem of finding persons equipped to train deaf mutes.

Medical School Inspection in Chicago.—The medical inspectors of schools in Chicago made physical examinations of 5,747 school children during the week ended October 3, and of these 2,450 were advised to seek surgical or medical treatment. The defects found were as follows. Nutrition, 143; anemia, 208; enlarged glands, 748; nervous diseases, 49; cardiac diseases, 56; pulmonary diseases, 34; skin diseases, 101; orthopedic, 96; vision, 899; hearing, 124; nasal breathing, 240; palate, 30; teeth, 1,620; hypertrophied tonsils, 1,068; adenoids, 198; mentality, 61. The total number of examinations made in the schools was 9,429, and the number of children excluded on account of contagious diseases was 372. The principal causes of exclusion were: Diphtheria and contact with diphtheria, 20; scarlet fever and contact with scarlet fever, 16; tonsillitis, 55; pediculosis, 105; impetigo, 87; ringworm, 17; measles, 6.

New York's Pure Food.—More than 11,000 tons of foodstuffs, with an estimated value of $1,500,000

have been destroyed by the food inspectors of New York within the last year in their efforts to insure wholesome supplies. The greater part of the destroyed goods consisted of fruit and vegetables, though a large amount of canned foods was also confiscated. The work is under the direction of Bayard C. Fuller, head of the division of food inspection of the Department of Health.

The Woman's Hospital of Philadelphia has arranged for the construction of a new building for a children's ward. The building will be three stories high, with a basement, and provision will be made for the addition later of two more stories. It will be of red brick, with blue marble trimmings of Colonial design, and it will be fireproof throughout. There will be accommodations for eye, ear, throat, medical and children's clinics, with wards and bathrooms on each floor. There will also be a diet kitchen and an *x*-ray laboratory.

Emanuel Church Movement.—St. Mark's Church in this city will, it is announced, open on October 18, an extension of the Christian healing movement which has its headquarters in Emanuel Church, Boston. It is said that a large number of patients from New York and Brooklyn go to Boston for treatment, and it is understood that the Boston leaders are cooperating in this new undertaking, which will be known as the Healing Mission of St. Mark's.

Street Car Accidents in New York.—The report to the Public Service Commission regarding street car accidents in New York during the month of August shows that forty-four persons were killed, and 3,317 injured in that time. Of these, 1,233 were injured while alighting from the cars; 15 suffered fractured skulls, and thirty-four broken limbs.

Anti-Vaccination in Massachusetts.—Mr. John H. Bonner, lecturer and organizer for the National Anti-Vaccination League of England, has recently been traveling through Massachusetts speaking before large public meetings on the "tyranny" of the Massachusetts law on vaccination, and on the "fearful cruelty" to animals which the process entails.

Public Milk Booth.—Plans have been submitted to the Building Department in New York for the big new milk booth to be erected by the city in Tompkins Square, for the distribution of sterilized milk. The building is to be octagonal in shape, twenty-nine feet in diameter and eighteen feet high, with an ornamental roof. It will contain a complete plumbing plant.

Loomis Annex Benefit.—The entire proceeds of October 7 from the Electrical Show at Madison Square Garden, New York, were donated by the management to the Loomis Sanatorium at Liberty, N. Y. In the evening lectures describing the work of the sanatorium among tuberculous patients were given.

Charitable Bequests.—The Bryn Mawr (Penn.) Hospital receives $5,000 by the will of the late Michael Callahan of Norristown. By the will of the late Miss Anne Van Reed $6,500 is bequeathed to the Medico-Chirurgical Hospital of Philadelphia.

Mt. Sinai Hospital and the Montefiore Home for Chronic Invalids each receive $1,000 under the will of the late Miss Eleanor Hendricks of New York.

The Health Protective Association of New York is made one of the residuary legatees of the estate of Miss Theresa Barcalow, who died last June. The value of the estate has not been announced.

The University of Texas Medical School opened on October 1, with over 200 matriculated students. The opening address was delivered by Dr. Terrill, professor of pathology.

Dr. G. Sims Woodhead, of Cambridge, England, delivered the Wesley M. Carpenter lecture at the Academy of Medicine on October 8. Dr. Martinez-Vargas of Barcelona, who was to have delivered this lecture was unable to be present. A large part of the audience was made up of delegates to the International Congress on Tuberculosis. A number of the foreign delegates have been spending a few days in New York, and have visited the Quarantine Station, Sea Breeze, Ellis Island, the Rockefeller Institute, and Bellevue Hospital, under the guidance of several New York physicians.

Mr. Rudyard Kipling delivered the usual address to the students at the opening of the Middlesex Hospital of London on October 1. Mr. Kipling divided mankind into two classes—doctors and patients, and admitted that he had had some delicacy in confessing that he belonged to the patient class since a doctor had informed him that all patients were phenomenal liars where their own symptoms were concerned.

Dr. Anne H. Thomas has been elected instructor in physical diagnosis and therapeutics in the Woman's Medical College of Pennsylvania, and she has also been appointed assistant physician at Bryn Mawr College.

Dr. Charles Adams of Chicago was appointed Surgeon-General of the Illinois National Guard in an order issued October 9 by the Governor of Illinois through Adjutant-General Thomas W. Scott. He succeeds the late Dr. Nicholas Senn.

Mr. Frank E. Wing has been elected superintendent of the Chicago Tuberculosis Institute to succeed Alexander M. Wilson.

Dr. John F. Erdmann has been appointed Professor of Surgery in the New York Post-Graduate Medical School and Hospital, and has resigned his Clinical Professorship in Surgery at the New York University and Bellevue Hospital Medical School.

Removals.—Dr. Otto Kiliani has removed to 50 West 77th Street. Dr. Charles H. Jaeger has removed to 471 Park Avenue.

Clinic for Speech Defects.—A clinic for speech defects (stuttering, stammering, etc.), has been opened at the New York Throat, Nose and Lung Hospital. It is under the direction of Dr. E. W. Scripture, and is held at 4 P.M. on Mondays, Wednesdays, and Fridays.

The Neurological Society and the Academy.—At a meeting of the New York Neurological Society, on October 7, a committee appointed by the President to consider the circumstances attending the reading of a paper upon the treatment of locomotor ataxia, at a recent meeting of the New York Academy of Medicine, made the following report: "Your Committee expresses disapproval of the occurrences following the reading of Dr. Denslow's paper. It is the belief of your Committee that papers which express radical views should be freely discussed at the time of their presentation and that every effort should be made to prevent the publication in the newspapers of communications which set forth promise of cure of diseases which are generally held to be incurable. Your Committee further believes that before such 'cures' are exploited they should be submitted to the most rigid investigation.

Oklahoma Medical Laws.—The new laws in

Oklahoma went into effect August 25 and September 25. On August 25 Dr. J. C. Mahr of Shawnee was appointed State Commissioner of Health, and on September 25 the new State Board of Medical Examiners was appointed. The medical license law requires that all schools shall be recognized, the Regulars to be entitled to four, Homeopaths two, Eclectics one, Physio-Medics one, Osteopaths one. This Board is constituted as follows: Drs. W. T. Tilly, *President,* Muskogee, A. M. Chambers, Poteau, A. M. Butts, Holdenville, and A. E. Davenport, Oklahoma City, Regulars; Drs. J. Hensley, Oklahoma City, and R. M. Miller, *Treasurer,* Blackwell, Homeopaths; Dr. F. P. Davis, *Secretary,* Enid, Eclectic, and Dr. A. C. Montague, *Vice-President,* Muskogee, Osteopath. The Physio-Medic member of the Board has not yet been appointed. The first regular meeting for the purpose of examining applicants for a medical license will be held in Muskogee, on November 6.

Tuberculosis Exhibition in New York.—Through the efforts of Dr. Alfred Meyer of this city, the exhibit, which formed so attractive and instructive a part of the International Congress on Tuberculosis in Washington, will be brought to New York.

The International Association of Medical Museums held its second meeting in the new building of the National Museum in Washington, D. C., on October 1 and 2, 1908, in connection with the International Congress on Tuberculosis. At this meeting a constitution was adopted and the following officers were elected: *President,* Prof. W. G. MacCallum, Baltimore; *First Vice-President,* Prof. G. Sims Woodhead, Cambridge, England; *Second Vice-President,* Prof. J. Ritchie, Edinburgh, Scotland; *Third Vice-President,* Prof. Ludwig Aschoff, Freiburg, Germany; *Secretary-Treasurer,* Dr. Maude E. Abbott, Montreal; *Councillors,* Major F. F. Russell, Washington, and Prof. A. S. Warthin, Ann Arbor, Mich. Since its first meeting the association had suffered a great loss in the death of its president, Dr. James Carroll of Washington.

The American Society for Humane Medical Research has recently been incorporated, the objects of the society being given as the conducting of clinical and laboratory research in medical science, the maintaining of chemical, physical, biological and physiological laboratories, and also the maintaining of an office and a statistical bureau in New York. Among the incorporators is Mrs. Diana Belais, President of the Anti-Vivisection Society. The list does not include the name of any physicians.

Medical Society of Virginia.—The thirty-ninth annual meeting of this society will be held in Richmond on October 20-23, 1908, under the presidency of Dr. William Francis Drewry of Petersburg. The secretary is Dr. Landon B. Edwards of Richmond.

The First District Branch of the Medical Society of the State of New York will hold its second annual meeting in Poughkeepsie on Wednesday, October 21, under the presidency of Dr. S. W. S. Toms of Nyack. The secretary is Dr. C. E. Denison of New York City.

The Binghamton (N. Y.) Academy of Medicine, which passed out of active existence some time ago, was reorganized on September 29, the following officers being elected: *President,* Dr. John H. Martin; *Vice-President,* Dr. John S. Kelley; *Secretary,* Dr. Frank L. Allen; *Treasurer,* Dr. John C. S. Lappeus.

The Cumberland County (Me.) Medical Society held its annual meeting in Portland on September 30. The following officers were elected for the ensuing year: *President,* Dr. Owen Smith; *Vice-President,* Herbert F. Twitchell; *Secretary,* Dr. Howard Pingree; *Treasurer,* Edward W. Gehring; *Board of Censors,* Dr. Stanley P. Warren, C. W. Foster, F. H. Jordan, South Portland.

The East Tennessee Medical Society held its annual meeting on September 24 and 25, at Newport. The following officers were elected: *President,* Dr. E. R. Zemp of Knoxville; *Secretary-Treasurer,* Dr. William M. Copenhaver of Bristol. The next meeting of the society will be held in Greeneville.

Obituary Notes.—Dr. John P. Seibert of Chambersburg, Penn., died on September 18, from cerebral hemorrhage, aged 55. He was graduated from the Jefferson Medical College in 1875, and for more than thirty years had been interested in the preparation of vaccine virus as proprietor of the Franklin County vaccine farm. He had served for many years as physician to the Franklin County jail.

Dr. Robert Morris Gibbs, professor of natural science in Kalamazoo College, Mich., died on September 18, after a long illness, aged 52. Dr. Gibbs was graduated from the Rush Medical College in the class of 1879, and was an ornithologist and entomologist of high standing.

Dr. J. P. Harrison of Richmond, Va., died suddenly on September 20, at his home, aged 74 years. Dr. Harrison graduated from the University of Pennsylvania Medical School in 1853, and served during the Civil War in the Confederate army as assistant surgeon in the Richmond hospital.

Dr. George H. Grant of Richmond, Ind., died, supposedly from a self-inflicted wound, on September 21, aged 42 years. Dr. Grant was graduated from Rush Medical College in 1888, was a member of the Mississippi Valley Medical Association and the American Medical Association, and lecturer on surgery in the Indiana Medical College. He had for some time been in poor health.

Dr. J. R. Hamill of Guthrie, Okla., died at his home on September 25, from typhoid fever, aged 44 years. He was a graduate of Rush Medical College in 1887, a member of the Oklahoma State Medical Association, and a specialist in diseases of the eye and ear.

Dr. William L. Reed of Indiana, Pa., a graduate of the Cincinnati College of Medicine and a member of the American Medical Association, died suddenly at his home on September 26, aged 65. Dr. Reed was a veteran of the Civil War, and from 1888 to 1892 served as a member of the Pennsylvania State Legislature.

Dr. Benjamin Whitely of Catonsville, Md., died at the Union Protestant Hospital in Baltimore on September 26, aged 64. Dr. Whitely was graduated from the Jefferson Medical College in 1867, and was a member of the Medical and Chirurgical Faculty of Maryland.

Dr. J. B. McGaughey of Winona, Minn., died suddenly from cerebral hemorrhage on September 27, aged 65. Dr. McGaughey was graduated from the University of Michigan in the class of 1867, and had practised in Winona for over forty years. He had been a member of the American Medical Association for thirty-six years, secretary of the Winona County Medical Society since 1872, and president of the Minnesota State Medical Association in 1884 and 1885.

Dr. George F. Heidemann of Elmhurst, Ill., died on September 29 at his home, aged 70 years. He was graduated from the Rush Medical College in 1863, and served in the Civil War as assistant surgeon of the Fifty-eighth Illinois Volunteer Infantry.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

VACATION CLOSES—SCIENCE CONGRESS—DEATHS UNDER ANESTHETICS—FATIGUE, PHYSICAL AND MENTAL—RADIUM—MEDICAL INSPECTION OF SCHOOL CHILDREN—SLEEPING SICKNESS—OBITUARY.

London, September 24, 1908.

The vacation is practically over, as next week the schools will open. Teachers have nearly all returned and are occupied with preparations for the work of the winter session. The introductory lectures should be composed or well in advance. At the schools where they are discontinued other functions which have been substituted are giving a larger number of persons no little anxiety as to the hoped-for success of the gatherings and the still more earnestly desired numerous entries of freshmen.

The proceedings of the Scientists at Dublin continue to afford food for conversation. Some of the subjects are outside those demanding your attention, but of course not beyond the range of your studies. In each section the addresses of the presidents sum up much that is of interest to the general public, and as much may be said for many of the papers. The wealth of material is thus so great that only gleanings can be offered to you in this column. In the physiological section Dr. Hewitt had a paper on the "Prevention of Deaths Under Anesthetics," in which he enforced on the attention of the scientists and through them on the public the views he is known by his professional brethren to hold. He put clearly before the gathering the conditions and circumstances under which anesthetics are at present administered and argued that this department of practice must be raised to a higher level in order to protect the public. He declared that both in personnel and other respects the departments of anesthetics are inadequately equipped. Considering his own position as a teacher and anesthetist at two of our great hospitals, this seems rather a hard saying, for I know that his example and teaching have been followed at other institutions. He complains that the examining bodies neglect the subject which he would have them enforce on the attention of students by making it a part of the compulsory curriculum. Many will perhaps think there is quite enough for the student to do in the already crowded condition of his curriculum, and the mere addition of an extra course of lectures cannot accomplish much. Neither can the obligation to administer anesthetics to a certain number of patients—of course under the supervision of the teacher. It is not by this sort of regulation that our practitioners attain, as a rule, their well-known skill in midwifery. The rule remains, but cannot account for the ability to meet great emergencies which is seen on almost all occasions of the kind, even in remote districts.

The first reform that Dr. Hewitt advocates I heartily endorse, viz., to make it a penal offense for an unqualified person to administer anesthetics. But the same punishment should be extended to other breaches of the medical acts. In this particular assumption of medical work by the unlicensed there are exceptional emergencies which would have to be provided for, and the attempt to restrict practice more efficiently and so protect the public from fraudulent pretensions will not very soon succeed. Where legislation is necessary the delay is usually of years' duration. The General Medical Council was imposed upon us to deal with such things, but in spite of its costly doings the protection of the profession and the public has not advanced. I agree with Dr. Hewitt that there is ample material in our hospitals for instruction in this and other subjects, but I think he underestimates what is being done. As a rule students are anxious to avail themselves of this "ample material." Another suggestion for reform is also a good one—the registration of all administrations at hospitals, specifying the anesthetic used and the result—so that the death rates of all agents could be compared.

I must add a line or two on the point which brought the paper within the program of the section. Acknowledging the work of Walter and other physiologists, Dr. Hewitt said many pin their faith on the adjustment of the vapor percentage, but he could not accept that as sufficient to secure safety. Could we in the human subject introduce our gases below the glottis their administration might be as safe in the operating theater as in Waller's laboratory. But we cannot, and unless there is just as free a lung ventilation when a one or two per cent. chloroform vapor is inhaled through the oronasal opening as when it is given through a cannula in the trachea, it is not to be inferred from animal experimentation that the danger in surgical practice is no greater. Dr. Hewitt expressed a desire that a small committee of physiologists would watch the difficulties that sometimes arise in the operating theater. He further urged the necessity of preventing the slightest obstruction to the free entry of air and of its free exit throughout the anesthesia, and further the selection of the appropriate agent to meet the requirements of the individual case.

A paper by Dr. W. MacDougal in this section dealt with fatigue, both mental and muscular. The writer said fatigue was not absolute, but relative. Sleepiness or tiredness coming on when engaged in some kind of work could be removed by another kind, e.g. heavy literary reading when it produced weariness or inattention would at once pass away on turning to lighter literature or exciting news. Fatigue, then, was a ratio between resistance and energy. In this way some pathological conditions could be explained. For health we needed to preserve the balance between resistance and energy so that when the resistance was below par there would be a tendency to excitement, fatigue, and slow recovery.

Mr. Sackville Lawson read a paper on some aspects of mental fatigue. He had applied the esthesiometer for experimenting as to the possibility of measuring mental fatigue. As it determines the loss of skin sensitiveness, he thought it might serve as a guide to the degree of mental energy expended. He found that a person may feel tired and yet be physiologically fresh. On the other hand, he may have the feeling and the esthesiometer may corroborate his sensations. Mr. Lawson suggested hard work as the best remedy for neurasthenia when the esthesiometer does not confirm the patient's symptoms. This nerve affection of which so much is heard nowadays is to be the "accidic" of medieval times, which Chaucer calls the "roten sin which maketh a man hevy, thoughtful, and wrawe, and full of sloth, wanhope and sompnolence." It would seem that "accidic" was sometimes mere sluggishness, when Mr. Lawson's remedy would be very effective. But we need not therefore deny that there are cases of neurasthenia which have another origin.

Everything relating to radium is so intensely interesting that you may not be surprised to know that the presidential address in the Geological Section in which it was dealt with is being spoken of as perhaps the most important contribution to science of this year's congress. Professor Joly said, uranium being the primary source of the supply—"the grandparent" of radium—we must look to that source, but there is no fear of a suspension of the supply. The uranium of the earth one hundred million years ago was hardly one per cent. more than it is to-day, and the fraction which is transformed in a year can only be estimated in tens of thousands of millionths. The interior of the earth may not be so rich in radium as the surface, but it exists far down and its presence in meteorites points to existence in that greatest of meteorites—the sun. Assuming a highly heated interior of the earth, Professor Joly saw no objection to the view that the loss of earth-heat may be supplied by radium and future cooling controlled by the transformation of uranium. Investigations already made show that radium and temperature are roughly proportionate. Professor Joly entered at length on the researches concerning the radioactivity of igneous rocks and the sediments of the beds of the oceans.

Sir A. Geikie declared the address was an epoch-making one and that the study of radium would probably help the solution of such problems as the earth's age and the upheaval of mountain ranges.

The circular of the Education Board lately sent to the local authorities on the medical inspection of school children has met with a varying reception. There are those who applaud every step in the direction of providing the children with all that their parents ought to supply and others who are asking anxiously where are we to stop? The ratepayers are in many places getting restive under the enormous burdens placed upon them in the name of education. Free instruction, free meals, etc., seem about to be followed by free medical attendance. As to this there is to be "a school medical officer" in every education area to be the head of a service of doctors, nurses, attendance officers, and teachers. He and his staff are to inspect and report on the improvements required in the school buildings and surroundings, lessons in hygiene, physical exercises, and so on. He is to advise as to baths and open-air schools. Further school clinics may be

established for further and more scientific examination of cases in which the medical inspection has shown defects in a child which cannot be conveniently investigated at the school. This looks like the establishment of a series of dispensaries or small hospitals at the cost of the ratepayers, and must, if carried out, lead to enormous and expensive changes. Only children are to be admitted to these clinics who cannot obtain the treatment needed at hospitals or the Poor Law arrangements. But this will mean little, and, as one objected, the extent of medical aid *gratis* will in a year or two be tremendous. The "school medical officer" is to be subordinate to the Medical Officer of Health, and this will bring the work into the Public Health Service. Is he to be well paid? is already asked. More important is the question whether he is to have security of tenure or be at the mercy of small local boards. He will have to prepare volumes of reports and statistics, but these will be of the usual useless kind, for the central board could not peruse them, still less digest such a mass within the year of issue.

It was announced on Tuesday that negotiations which have been in progress for some time between this country and Germany for the conclusion of a treaty to combat sleeping sickness are practically complete. A convention for a period of three years provides for the establishing of segregation camps on each side of the boundary between British and German possessions in Africa. Doctors and officials of the respective camps will keep in touch and compare the results of their researches. Infective natives will be prevented from passing to uninfected districts. They will be detained and segregated. Notification to the officials of both Governments is to be made of all infected areas and effective measures are to be taken for dealing with crocodiles or other animals which may be found to be the food of the parasite.

Dr. Walter Brown, physician to the Gloucester General Infirmary, died on the 12th inst. He qualified at the two London colleges in 1874-1875 and subsequently graduated at Aberdeen, 1879.

Dr. S. W. Bushell, late physician to the British Legation in Peking, died on Saturday at the age of sixty-four. He was a London graduate, B.Sc., M.B., M.D., at each stage taking honors. He was a gold medalist, exhibitioner, and university medical scholar. He held resident appointments at Guy's and Bethlehem Hospitals. In 1868 he was appointer to the Peking Post, which he held until 1900. He was created C.M.G. in 1897. He wrote a work on "Oriental Ceramic Art" and contributed to allied subjects, and was a Fellow of various scientific societies.

DOCTORS VERSUS NEW IDEAS.

To the Editor of the Medical Record:

Sir:—When Dr. Denslow's observation on the subject of locomotor ataxia appeared in the lay press, together with the comments of various colleagues, the editor of one of the most substantial newspapers wrote: "For our part, we cannot see the danger of giving hope, even illusive, to the man or woman burdened by a deep despair." This is no doubt the conventional lay view, and apparently a common-sense one. It is the chief obstacle which doctors meet when trying to prevent medical sects from obtaining legislative favors.

There are two sides to the question. Doctors have to protect the public against the multitude of fanciful theories and untried methods that are constantly being foisted upon the profession by earnest advocates, as well as by designing charlatans.

When a doctor comes forward with a new idea, it promptly oversets established ideas which are being employed in daily routine by good doctors, for helping the people who have put trust in them. It hurts honest men, by calling into question their wisdom in previous choice of method. They are bound to attack a man who comes forward with a new idea, and to ask him to defend himself. Their attitude is really impersonal in primal conception, and is in the interest of their patients, but it seems very personal to a man who is vain and weak. Most new ideas are batted down, and they belong down. We know of men who have been subjected to persistent and bitter attack almost from their first entrance into the profession, because they happened to be men of inventive talent, who could not help being constructive along new lines. It has cost them thousands of dollars a year, and has even reached a question of their personal characters, and has interfered with their entrance into some social clubs. This is as it should be, in accordance with existing conditions. When the people can no more be prevented from rushing to charlatans than horses can be turned back from burning barns, the doctor who comes forward with a new idea must stand the searching questions which extend clear down to the fish stories with which he amuses his friends. The doctor who plans a life devoted to new work must be fundamentally altruistic, and must find his chief compensation in the gratifying knowledge of the fact that he is molding professional opinion for the benefit of the public. He must be prepared, after carrying a new idea over the goal, to have it appropriated by others, who will forget that he did anything more than to create a disturbance—they have forgotten just what it was. All of this is acceptable to the doctor who is working in the true professional spirit. He must stand punishment like a football player, and must keep better natured.

The editor whom we have quoted rebukes the doctors who have attacked Dr. Denslow, and says that they should have waited until they had read his Academy paper before criticising him. How about the hundreds of sufferers who will not wait for the Academy paper? Our point of view is that no one should have had the subject for discussion before the Academy paper appeared. In the present instance it seems probable that a new idea has been developed successfully, but how about the multitude of ideas that have at various times gotten into the lay press in advance of proper publication? Thousands of sufferers in the past have been given vain hope, and have been plunged into the depths of despair. Thousands of people have expended upon false prophets the dollars which they needed for ordinary comforts. Doctors will protect the public against this sort of thing if the public will allow itself to be kept out of burning barns.

Acute Appendicitis in Children.—B. Vincent discusses the various features of the disease as occurring in children and summarizes her views as follows: Acute appendicitis is rare in infancy but is more common in childhood than is generally supposed. An early diagnosis is difficult and the first stages and lighter forms of the attack may be easily overlooked. The prognosis of the disease is more rapid in children than in adults; the involvement of the peritoneum and the appearance of pus are early features; diffuse peritonitis is probably more frequent, but there is still greater tendency to the formation of a localized abscess. A child is never so young and seldom so sick as to contraindicate surgical interference, but the extent of the operation must always be measured by the condition of each patient. Children stand short operations well, but may be needlessly lost through prolonged and ill-advised efforts to do more than is absolutely essential. The prognosis is more uncertain in children than in adults. Age is a very important factor. In children over ten years of age the prognosis is at least as good as in adults; in children under five years it is worse, and in infants the prognosis is exceedingly grave.

Measles in Utero.—N. E. Mason reports the case of a primipara of 19 years, who entered the hospital with a distinct measles rash which subsided in eight days after admission. At this period she was delivered by forceps. The child presented a mottling of the skin over the entire body and a branny desquamation over the chest and in the axilla. On the following day desquamation appeared over the forehead, on the plantar surface of the toes and between the toes. On the second day there was more profuse desquamation over the chest and face, being of a markedly furfuraceous character on the sides of the nose. Desquamation was also present upon the abdomen. On the thirteenth day very slight, fine desquamation could be seen over the temples and in the axillæ. On the seventeenth day fine desquamation could still be detected in each lower axilla. On the twenty-first day desquamation had completely disappeared and there was no sign of infection with measles. Mother and baby were discharged well from the hospital on the twenty-third day after delivery. The author quotes from various writers on pediatrics relative to such cases as his own. The main question in dispute arises over the fact as to whether the child has a true measles desquamation or the normal exfoliation of the newborn. Then, also, there is the notable fact that although the mother nursed the child and both remained in the measles ward, the child did not contract the disease, which it probably would have done had it not been for the recent attack. Most writers apparently regard the transmission of measles from mother to fetus as a very rare occurrence, but more doubt its possibility.

New York Medical Journal, October 3, 1908.

Apoplexy in the Classification of Diseases.—F. P. Foster makes a plea for the retention in the forthcoming classification of diseases by the American Public Health Association of the term apoplexy as signifying an affection of the nervous system. Some physicians think that apoplexy should be classified under diseases of the vascular system in mortality returns and death certificates. To make the change would be impracticable and illogical. The present international classification ranges malignant neoplasms by themselves, regardless of their situation; but it deals with benign tumors according to the part which they occupy. I think that this is correct. Apart from the displacement of fragments of bone, fractures of the skull owe their gravity to hemorrhage from an intracranial vessel which has been torn in the injury, but would anybody dream of treatment of such cases under the head of injuries of arteries? Tuberculous infection varies in its gravity according to the part involved, though the invading organism is the same in all instances. We dread the pulmonary and the meningeal manifestations much more than those of the spinal column, the joints, or the lymphatic glands, and in practice we do not associate them all together. It is the part affected that is of the greatest practical importance, and in the case of apoplexy it is the fact that the brain is involved that is the significant feature.

Repair of the Perineum.—The main thesis of J. W. Henson's paper is that in repairing the perineum it is just as important to search for and thoroughly suture the several bands of the levator ani muscle as it is in complete laceration to find and bring together the ends of the sphincter ani. The author does not laud any particular operation. If it accomplishes the aim referred to it is satisfactory; if it does not, it will fail to give the permanent relief sought. As a matter of fact, the author prefers the flap-splitting method, because thereby the muscles can be easily reached and because no tissue is lost. He regards the redundant tissue idea as only a bugaboo. Detailed technical features are the following: The incision, as it is carried up on each side of the vaginal orifice, is inclined within the latter just enough for the anterior margin of the new perineum, after the sutures are tied, to be a little back of the meatus so that upon micturition the urine is conducted off by the perineum as a gutter, none of it trickling into the vagina, as it frequently does after perineorrhaphy by other methods. In introducing the sutures the needle is made to avoid puncturing the skin as it is passed in, and the mucous membrane as it is brought out, or *vice versa*. Thus the suture can take more of the muscular tissue in its grasp, and furthermore, it does not cut and get loose as sometimes happens when skin or mucous membrane is caught.

Apoplexy: Its Causes and Treatment.—The familiar clinical appearances of apoplexy are set forth by J. D. Bonnar, who discusses also the pathological changes in the brain tissue, course of the disease, prognosis, and differential diagnosis. Concerning treatment, he says that nature attempts to stem the ebbing tide at first by increasing the intracerebral pressure, by equalizing the arterial pressure. The head should be lowered in embolism, but raised in apoplexy. The value of cold packs to the head is a measure of disputed value. Venesection is advisable when there is a rush of blood to the head, in middle-aged men with arteriosclerosis, accentuated second aortic sound and hypertrophied left ventricles. Purgation is good in apoplexy, but not in embolism. Aconite may be used in the fever of reaction. While doubting somewhat the efficacy of internal remedies, the author uses bromide of potassium with ergot and a mild aperient. He also advises in prodromic symptoms of apoplexy deep inspirations, so as to withdraw to the thorax the blood pressure bearing on the brain. A little food should be given. The swollen limbs should be warmly wrapped. Ether, digitalis, and ammonia may be given for weak heart. A specific case calls for the free use of the iodide. Later massage and electricity may be employed. The patient's friends should be informed that in complete hemiplegia the leg may recover, but that the hand rarely recovers finger movement. After middle life mental weakness, irritability, and emotionalism are apt to persist. If distinct improvement is not noted after three months, the case is generally hopeless. Unless collateral circulation does not sufficiently nourish the affected brain area within forty-eight hours, the brain focus will probably remain permanently softened and topical disease will result.

Irremovable Cancer.—This question is discussed by W. S. Bainbridge under the headings of (1) seemingly irremovable, (2) operable, but irremovable, yet curable, and (3) operable, but irremovable and incurable. Under each heading typical cases are described and illustrated by some excellent photographs. Under the first heading the author says that the case may be inoperable, yet the cancer *per se* may be perfectly amenable to operation (1) on account of the patient's condition in other respects than as regards the cancer. If the contraindication condition is temporary, measures should be instituted for its removal. Proper care may render the case both operable and removable. (2) Concurrent complications in the neighborhood of the cancer may lead to the diagnosis of irremovable malignancy. Many times the growth may be complicated by septicemia and sapremia and it is to these rather than to the neoplasm itself that the immediate desperate condition is due. If these can be controlled the case assumes an entirely different aspect. Under the second heading the author says that the word curable as applied to cancer is a relative term. Strictly speaking, we do not cure cancer; we remove it and in the vast majority of cases, when it is impossible to remove it, it is impossible to cure the patient. Statistics amply justify the so-called three-year limit. In still another limited number of cases of advanced cancer which is operable, but in which it is impossible to remove the entire growth, by removing as much as possible and instituting other measures, nature seems to be able to cope with the malignant process and to reduce it to such a state of subjugation that it disappears or remains so completely quiescent that the patient lives a number of years and is to all intents and purposes cured. Under the third heading we have at our disposal the following procedures: (1) General treatment of the patient, (2) treatment of the indirect conditions caused by the cancer. Thus: A malignant tumor may cause obstruction of the nose, for example, of the esophagus, of the stomach, etc., and to relieve this obstruction it may be necessary to resort to tracheotomy, esophagostomy, gastrostomy, enteroenterostomy, etc., as the case may be. In case of obstruction of the bladder suprapubic cystotomy or perineal drainage may be necessary. (3) We may ligate the blood-vessels in the carotid region (the Dawbarn plan). (4) We may ligate vessels in the pelvis in inoperable uterine and other pelvic cases, as it lessens the danger of hemorrhage, decreases fetor, and renders it possible to proceed with the necessary surgical intervention, such as curetting, cauterizing, etc. It also diminishes the rapidity of growth in some instances, lessens pain, and frequently prolongs life. (5) Other plans may be followed, as the use of the *x*-ray, high-frequency current, fulguration, leucodescent light, radium, mixed toxins (Coley's fluid), *Streptococcus pyogenes* (Wyeth), oophorectomy, and pancreatic enzymes. Finally, the author devotes some space to the matter of caring for the absolutely hopeless cases, those which are inoperable, irremovable and incurable. Under this are enumerated the various measures for controlling pain, keeping the fungating masses clean, etc. Alcohol may be taken with food. More of these cases present a hyperacidity and alkaline waters are beneficial. Acetphenetidin in doses of 10 to 15 grains twice daily combats pain very well. Something should be given with morphine to counteract its bad effects. Atropine may be added if the patient sweats. The U. S. solution of morphine may be combined in long-continued cases with elixir of lactopeptin.

Journal of the American Medical Association, October 3, 1908.

Prolapse of Rectum.—L. J. Hirschman reports two cases of hysterectomy which emphasize one of the sequels of this operation, which, he thinks, has not received sufficient attention. In both cases there was more or less rectal prolapse which required a second operation. From these two cases he deduces that in patients requiring hysterectomy, who have suffered from chronic constipation, the possibility of postoperative prolapse of the rectum and sigmoid must be considered. In such patients the removal of the uterus deprives the rectum of an important anterior support, and the broad ligaments should be brought together whenever possible. Further, if in these cases laceration or rectocele exists perineorrhapy and posterior colporrhaphy should be performed. If there is any tendency to prolapse of the rectum or sigmoid, mesosigmoidopexy should be done as a prophylactic measure. Mesosigmoidopexy should be the operation of choice in any case of complete prolapse of the rectum or sigmoid, whether following hysterectomy or from other causes, "as it holds the sigmoid in place by its natural support, its own mesentery, which, being double its original thickness, becomes twice as strong a support. By not causing a fixation of the bowel to the abdominal or pelvic wall, its natural mobility is not interfered with, and the normal peristaltic movements are not interfered with."

Cervical Ribs.—J. B. Roberts calls attention to the disturbances that may be caused by cervical ribs in producing vascular and nervous lesions of the neck and upper extremity, and reports an illustrative case in which a rib

gave rise to suspicion of the existence of an aneurism. It behooves physicians, he says, to remember that pain, anesthesia, muscular spasm, defective circulation and atrophy may be due to pressure in the supraclavicular triangle of the neck by an anomalous rib connected with the sixth or seventh cervical vertebra. He describes the various forms which these growths may assume and the symptoms they may produce. The determining cause of the advent of symptoms is obscure; it has been supposed that there is a tendency for these ribs to increase in length about the third decade of life by the development of exostoses, but the symptoms have been observed to develop suddenly in children as well as in adults. Those that extend directly outward from the spine seem to cause less trouble than those that point downward, and the longer ones than the short, stumpy ones. This is perhaps due to the fact that more perfectly shaped ribs cause less disturbance than the more abnormal ones. The treatment is excision in all cases in which the symptoms are severe. The operation, properly done, is practically safe, though it naturally varies in surgical importance in different cases. The palliative treatment in mild cases consists in rest of the arm, suspension of the patient, local counterirritation and massage. Electricity may also be useful.

Posture in Treatment of Rectal Disease.—G. S. Hanes reports that he has employed as nearly complete inversion of the patient as possible in the treatment of rectal and sigmoid conditions, with results better than could be otherwise obtained. The patient is placed on the table with the foot rest dropped and is allowed to hang over the end of the table on his thighs, with either the right or left shoulder resting on the edge of a plain chair, the other hand resting flat on the floor, or, still better, the patient is allowed to rest his head on a pillow, folding his arms and supporting his weight on each elbow. He has often kept patients in this position, he says, for from ten to twenty minutes with comparatively slight discomfort to them. As soon as the patient assumes the position, the abdominal viscera gravitate toward the diaphragm and the maximum tension on the sigmoid and rectum is obtained, the bowel approximating a straight line. The use of instruments with the least possible injury is thus facilitated. The article is illustrated.

Submucous Resection of Nasal Wall.—R. B. Canfield describes and illustrates an operation for the relief of intractable cases of antral empyema, simple or combined with ethmoid or sphenoid disease, that have resisted less radical methods. It includes, after local anesthesia with cocain and adrenalin: (1) Incision through the soft parts of the nostril at the inner margin of the vestibule, beginning about the middle of the lateral wall of the pyriform opening and extending well down to the floor of the nose. The incision passes through the periosteum, which is incised along the lateral wall of the pyriform opening. (2) Raising the mucous membrane and periosteum of the lateral wall of the nose from the floor upward to the level of the attachment of the inferior turbinate and backward as far as convenient. (3) Elevation of the periosteum of the anterior antral wall for any desired distance. (4) Removal of the pyriform opening and the lateral wall of the nose over the area where the mucosa has been raised so that the floor of the nose is continued outward into the antrum without irregularity. (5) Enucleation of any desired amount of the inferior turbinate without disturbing the soft tissue. (6) Removal of the desired amount of the anterior antral wall, *i.e.*, enough to allow view of the antrum. (7) Penetration of the lining membrane of the antrum and inspection of its cavity. (8) Curettage of the antrum if needed. The ethmoid is then entered, if necessary, after enucleating the bone of the middle turbinate, making it easily movable and permitting access to the ethmoid bulla and anterior ethmoid cells, which can be thoroughly curetted. If removal of the anterior wall of the sphenoid is required, it can now be brought in sight, in the absence of a septal deviation toward the affected side, by pressing the soft tissues of the turbinate laterally into the region of the ethmoid. (9) Formation of a flap of mucous membrane from that part of the lateral wall of the nose beneath the level of the attachment of the inferior turbinate, removal of the deepest portion of the median wall of the antrum to insure good drainage. Careful approximation of the mucous membrane flap to the floor of the antrum and packing the nose and antrum with vaselin gauze complete the operation. The after-treatment is very simple. The gauze is removed on the fourth or fifth day and the operative field is inspected and wiped dry. Some cases require nothing more. Sometimes a little granulation tissue calls for the curette or silver nitrate. Canfield claims certain advantages for this operation: it can be performed under either local or general anesthesia; can be as simple or radical as desired; calls for no buccal incision and little bruising of soft tissues; affords the most satisfactory view; can be performed in several steps if desired and simplifies the after-treatment. The results have been satisfactory in his experience of the twelve cases in which he has performed it.

Anemia of Hepatic Cirrhosis.—J. E. Talley reports two cases, one rather conclusive, the other suggestive at least, of hepatic cirrhosis without hemorrhage terminating in pernicious anemia. That such a change should occur in the blood is easily conceivable, he says, when it is remembered that both hepatic cirrhosis and progressive pernicious anemia are probably due to infection. In any case, secondary and primary, or pernicious, anemia are but relative terms. Many of the cases formerly classed as primary latterly have been found to be secondary, the cause having been demonstrated. The differences in the blood findings are moreover largely those of degree. Hemolysis and hematogenesis are present in both. A limited amount of metaplasia may occur in the marrow in marked secondary anemia; occasionally it is absent in pernicious anemia. Usually, however, it is only when marked destruction of imperfectly formed blood corpuscles begins that the true picture of the pernicious type appears.

British Medical Journal, September 12 and 26, 1908.

Bulbar Paralysis Followed by Progressive Muscular Atrophy.—The case is reported by J. F. Little and T. J. Bokerham who believe that the application of intermittent electric currents at high tension by means of electrodes impregnated with drugs capable of introduction by the plan known as "ionic" medication caused an actual improvement in the symptoms referable to the bulbar lesion. The course of the case is well described in the title of the paper, and there was nothing unusual in the symptomatology which suggested to the authors the existence of changes not only in the nuclei of the bulb, but in addition lesions in the anterior gray cornua of the cord. The patient is an electrical engineer of thirty-four years and his symptoms dated back four years, the first thing noted being an inability to whistle. The disease ran its usual course and the patient at the end died quietly as if falling asleep. A full description is given of the various systemic symptoms together with an enumeration of the various electrical reactions.

X-Ray Dermatitis and Its Prevention.—J. F. Han-Edwards, a sufferer from this affection, gives a full account of his own case. The hands were particularly affected and their condition is shown by radiographs. It is interesting to note that the phalangeal bones became involved and that amputation of one forefinger was necessary. The ideal method of protection, says the author, must be one which so cuts off the rays that they emanate only from an opening representing a portion of the surface of the tube and which is entirely under the control of the operator. He prefers to inclose his tubes in globes of thick lead glass and uses a Dean's shield. He also advocates the use of screens composed of wood covered with thin sheet lead, containing a window of lead glass of sufficient size to allow the operator to watch the patient during the exposure. He prefers to use the fluorescent screen as little as possible. In one of the first communications given to us in the early days of the *x*-rays it was pointed out that the interposition of an earthed aluminum plate placed between the *x*-ray tube and the operator or patient rendered the effect of the rays upon the skin inert. At the same time there existed some difference of opinion as to how far the rays, thus cut off, influenced treatment. There can be little doubt that the electrostatic field which surrounds an *x*-ray tube in action has considerable influence in the production of radiodermatitis. That this electrostatic field is diminished by earthing the anode pole is certain, and the author feels convinced that extra safety is secured by the earthing of all metallic conductors in this field. The first shields devised were made upon unscientific lines, and for this reason, while they protected the operator they failed to bring about satisfactory therapeutic results. Belot's shield was the first constructed upon sound lines, and it paved the way for the introduction of many pieces of apparatus which are more or less efficient. The author is convinced that the shield or protecting box for cutting off all rays from the tube, except those which are actually required for the purpose of diagnosis or treatment, offers the best method of protection, and I would advise every worker to adopt it. The position of the operator in relation to the tube is one of importance, and it should always be borne in mind that the safest place is behind the anticathode.

The Relation of Disease of the Accessory Nasal Sinuses to Diseases of the Eye.—A discussion of the subject occurred at the recent meeting of the British Medical Association and was opened by A. Logan Turner, who said that when we study the nasal sinuses we are struck with their intimate relation to the orbit. There is

not only a juxtaposition of long walls, but there is a direct intercommunication between the veins of the nasal cavities and the accessory sinuses on the one hand and the venous trunks of the orbit on the other. A direct lymphatic connection has not yet been established on anatomical grounds. From the foregoing statement it follows that septic processes in the nose and sinuses may easily invade the orbits. With reference to the cavities, we may divide the sinuses into the same anterior and posterior groups as we do when considering simply their nasal relations. Thus, anteriorly, the frontal sinus and anterior ethmoidal cells may occupy to a varying extent the roof of the orbital cavity in its anterior part. The anterior ethmoidal cells are in intimate relation to the anterior part of the inner orbital wall, while the maxillary sinus lies both anteriorly and posteriorly beneath the orbital floor. In relation to the posterior part of the orbit, we find that the posterior ethmoidal cells and sphenoidal sinus have a constant relationship to its inner wall. Occasionally a large posterior ethmoidal cell intervenes between the antrum and the floor of the orbit, while the roof of the orbit close to its apex may be slightly invaded by an exceptionally developed posterior ethmoidal cell. If we proceed a step further, and study the relation of the sinuses to the orbital contents, it is possible to maintain this grouping in connection with certain orbital and ocular phenomena which may have their origin in pathological conditions of the sinuses. Thus, when we meet with displacement of the eyeball, swellings in the inner and upper part of the orbital cavity and peridacryocystitis, the attention should be directed to the frontal sinus, anterior ethmoidal cells, and maxillary sinus. On the other hand, the existence of retrobulbar neuritis, optic atrophy, and paralysis of ocular muscles may result from diseases of the posterior ethmoidal and sphenoidal sinuses. In other words, affections of the anterior group of sinuses may be responsible for bulbar affections, while pathological conditions of the posterior group may be the causation of certain retrobulbar affections. It is true that a classification of this kind does not include all the ocular affections that may be secondary to diseases of the nasal accessory sinuses, nevertheless it forms a sufficiently useful working basis both for the ophthalmologist and the rhinologist.

Some Cases of Vaccine Therapy.—W. M. Crofton presents the clinical histories of four cases of, respectively, chronic pyemia, tuberculous disease of the hip-joint, eczema and sycosis, all of which recovered under the vaccine therapy. He concludes that it is legitimate to vaccinate patients with strictly localized infections without any estimation of the opsonic index. To confer any permanent immunity materially increasing doses are necessary. Given in such a way vaccines may prove to be of prophylactic value. Of the four cases detailed the opsonic index was estimated only in the first. The other three were treated without its estimation, the intervals being determined by the amount of local and general reaction. The first dose was always small and varied with the age and condition of the patient. As to increase of subsequent dosage the author says that in an adult case of localized staphylococcus infection the first dose would be: ½ c.cm. of a vaccine containing 200 millions cocci to the cubic centimeter, the next dose, as a rule a fortnight to three weeks after, 1 c.cm., the next 2 c.cm., the next 3 c.cm., the next 4 c.cm., and so on. He makes it a rule, if possible, to give a final large dose after the patient is apparently cured, and finds this has a potent influence in preventing relapse; the only relapses he has had were in patients who refused it.

Some Requirements of Modern Surgery.—C. H. Hough enumerates asepsis, antisepsis, the importance of a bacteriological training, therapeutic immunization, the Roentgen ray and the Finsen light. Concerning the matter of surgical bacteriology, he says that anyone who has been trained in a bacteriological laboratory will have exalted ideas of surgical cleanliness and will be sure to note the many inconsistencies which occur during the average surgical operation. Thus it is by no means uncommon to see those who are considered careful men touching with their hands after sterilization the face or hair, or permitting them to come in contact with some non-sterile article, such, for instance, as a blanket which protects the patient, an unsterilized instrument, or any portion of their own unprotected clothing. These inconsistencies may appear trifling to many, but unfortunately they are too often responsible for the introduction of infectious material into the wound. Though it may be true, as has been contended by some, that every wound made by the surgeon contains microorganisms, under ordinary circumstances the resisting power of the patient will be sufficient to prevent their growth and development. While admitting that an infection following operation must, with our present knowledge, be sometimes attributable to a lowered systematic resistance, and to no fault of the surgeon or his assistants, it must be understood that this is extremely rare, and that in nearly every case of sepsis a rigid analysis of the technique employed will bring to light some act of omission or commission to account for it. The author believes that a perfect technique can ultimately be obtained by submitting every step to the test of bacteriological examination, and that the surgeon who is able to work on these lines will, *cæteris paribus,* undoubtedly obtain the best results in his own operations.

Some Forms of Cardiac Arrhythmia from the Point of View of the Myogenic Theory.—W. J. Fenton discusses present-day theories of cardiac action, defining the myogenic theory as postulating the formation of the stimulus to the heart's contraction in the heart muscle cells themselves, and not as an impulse conducted to the cells from the nervous system. The fundamental attributes of heart muscle are stimulus formation and conduction of irritability and contractility. These have certain relationships to each other, and yet are capable of independent variations within wide limits. The co-operaton of these properties produces the rhythmical heart movements, but the adaptation to the varying needs of the body is brought about through the nervous system, acting on one or another of the muscle cell properties. Some portions of heart muscle may possess a given property in an unusual degree. The simplest form of arrhythmia is that disturbance of rhythm known as the extra systole. The so-called "heart block," or the Stokes-Adams disease, results from a defect in conductivity and the complete syndrome depends on the combination of two factors: (1) prolonged or permanent slowing of the heart beat with paroxysmal attacks of extreme bradycardia and (2) diseased cerebral arteries. Most cases presenting this disease syndrome of the auricular ventricular muscular bundle present either sclerosis, gumma or vascular disturbance. In some cases no gross lesion has been present. The best example of defect of contractibility is perhaps that of the "pulsus alternans," in which large and small beats are found in alternation in the radial pulse. When the contractility is lowered the heart's contraction is made more quickly than normal, that is, it does not last so long, the consequence of which is that the duration of the pause following the smaller contraction is longer than that following the larger one. But a longer pause will be followed by a larger and, therefore, longer enduring contraction by reason of the length of the rest allowed by the longer pause, and, conversely, a large contraction by lasting longer will be followed by a smaller beat. If, therefore, when the contractability is lowered the duration of a pause should be lengthened from any cause, while the cardiac rhythm remains otherwise unchanged, a pulsus alternans will be the result.

Deutsche medizinische Wochenschrift, September 24, 1908.

Indications for Operation in Compression Paralysis.—Bardenheuer says that subcutaneous traumatic compression may produce paralysis when it acts suddenly, and is of great intensity, as instanced by the injury to the brachial plexus through forced hyperabduction and rotation of the arm which are sometimes necessary in the reduction of dislocations of the humerus. Such compression may be less intense in degree and yet produce similar paralysis because of prolonged action, as instanced by the paralysis of the brachial plexus that sometimes occurs after narcosis. From the practical standpoint the difficulty lies in estimating the amount of injury produced, for the intensity of symptoms, that is, the degree of paralysis, is a very inadequate criterion. Yet such estimation is of great importance for operative treatment is called for in cases of severe compression of the nerves, while rest, massage and electrical treatment are sufficient to overcome minor injuries. Bardenheuer considers that operation is called for, if no improvement in the degree of paralysis takes place in two or three weeks; if the electrical irritability of the nerves disappears in ten to fourteen days after a short preliminary increase; if the muscles cannot be stimulated by the faradic current during the first week of paralysis, while an increased irritability to the galvanic current occurs in the second week together with the appearance of the reaction of degeneration and of atrophy. The operation may consist of baring the nerve, which diminishes the intranervous pressure and allows the escape of the lymph and blood gathered within the sheath, which often prevents the formation of scar tissue with subsequent interference with the regeneration of the nerve; in other cases simple splicing is indicated.

First Class in Inebriety.—A class of one hundred habitual drunkards in Richmond, Va., recently took a three-day cure under the supervision of a physician of the city who claims to induce a distaste for alcohol in that brief period.

Book Reviews.

The Spectroscope. Its Uses in General Analytical Chemistry. An Intermediate Textbook for Practical Chemists. By T. Thorne Baker, F.C.S., F.R.P.S., Author of "Spektralphotographie, und deren Anwendung," "Orthochromatic Photography," etc. New York: William Wood & Co., 1907.

The spectroscope has attained a very important place in the laboratories of physiological chemistry as well as of clinical pathology, its use furnishing the readiest means of determining the presence of blood, of bile elements, etc. The book under consideration aims to acquaint a worker in these fields who has some knowledge of general physics with the special questions involved in the formation of a spectroscopic image, the modern forms of the apparatus, and with the technique of spectrophotography. The book is necessarily technical in character, and is intended for the specialist in laboratory analysis and for the advanced student of physics as well. Any physician, however, using the instrument will obtain a clear idea by perusing this book of the principles and the theories upon which spectroscopic analysis is founded.

Aids to Osteology. By Philip Turner, B.Sc., M.B., M.S. (Lond.), F.R.C.S., Demonstrator of Anatomy, Guy's Hospital. New York: William Wood & Co., 1908.

This pocket volume is a competent compend on Osteology. There is, naturally, nothing new in such a volume; but the essentials of the subject are adequately represented, and the book will be a substantial help to many a first year student in his struggles with Gray or Cunningham.

The Blues (Splanchnic Neurasthenia). Causes and Cure. By Albert Abrams, A.M., M.D. (Heidelberg), F.R.M.S.; Consulting Physician, Denver National Hospital for Consumptives, the Mount Zion and the French Hospitals, San Francisco; President of the Emmanuel Sisterhood Polyclinic; Formerly Professor of Pathology and Director of the Medical Clinic, Cooper Medical College, San Francisco. Illustrated. Third Edition, Revised and Enlarged. New York: E. B. Treat & Company, 1908.

The author's novel views are again in evidence in this, his third edition. The main part of the work has simply been revised and enlarged while the author has added an entirely new note on the vasomotor test in splanchnic neurasthenia and a new chapter on intestinal autointoxication. Although much unproved theory abounds in the book it makes interesting reading, and may in the future lead to an improved method of therapy in these cases of "the blues." The author describes his technique carefully and gives the necessary illustrations such as are needed for thoroughly understanding the text.

Milatär-Sanitätswesen. Herausgegeben von der Medizinal-Abteilung des Königlich Preussischen Kriegsministeriums. No. 37: Ueber die Anwendung von Heil-und Schutzseris im Heere. Berlin: August Hirschwald, 1908.

In this work the value of many of the immunizing and curative sera are discussed. For use in the army during war only those are advocated which are prepared under government supervision. Diphtheria antitoxin should be taken along only in small quantities as diphtheria epidemics rarely occur during war. Tetanus antitoxin should be carried upon the battlefield in large quantities, it being most valuable as a prophylactic. As meningitis and dysentery epidemics frequently occur, meningococcus and dysentery serum should be carried in large quantities. The value of the latter two is still doubtful, though it is certain that they can do no harm. The Pfeiffer-Kolle method of using typhoid serum is considered the best for immunizing purposes. It, however, requires a week or longer to carry it out, and is therefore impracticable in an active army, excepting for nurses in typhoid wards. The sera mentioned have no bad after effects, can be preserved a long time, and can be made in large enough quantities for army use. For army physicians this contribution to literature will be especially valuable.

Insomnia and Nerve Strain. By Henry S. Upson, M.D., Professor of Diseases of the Nervous System in the Western Reserve University; Attending Neurologist to the Lakeside Hospital, Cleveland, Ohio. With skiagraphic illustrations. New York and London: G. P. Putnam's Sons, 1908.

In this little work the writer finds opportunity to set forth in the main, a provisional sketch of the mode of origin of the psychoses. He describes the action of the nervous system in its relation to inhibition, vascular control, nutrition, shock, etc., and formulates an ingenious hypothesis of a "vasoneural circuit." His view of the neuroses and psychoses in general, is that they are primarily irritative disorders of the sensory nervous system affecting the remainder of the nerve mechanism indirectly. He contends, therefore, that these conditions have a right to a better prognosis than is often ascribed to them in that their etiological factors are removable. As an illustration, skiagraphs of several maxillæ are shown, in which there were dental abscesses or impactions, removal of which caused recovery or improvement in the psychoses. In speaking of convulsive seizures, the writer states that motor convulsions are never critical, and that there can be no such thing as sensory or psychic epilepsy. This seems a step backward.

Klinik für Psychische und Nervöse Krankheiten. Herausgegeben von Robert Sommer, Dr. med. et phil., o. Professor an der Univ. Giessen. III. Band, 1. Heft. Halle a S.: Carl Marhold Verlagsbuchhandlung, 1908.

In this number may be found: An article by Knauer on the electrolytic potential and conductibility of the skin; two articles by Gregor, one with Zaloziecki, on the diagnosis of psychiatric processes in stupor; an article by Plönies on sleep disorders from stomach disturbances; and a scheme by Prof. Sommer for the examination of idiots and imbeciles.

Die Fehlergrösse bei den histologischen Methoden. Von Privatdozent Dr. med. W. Berg, Assistent am anatomischen Institut der Universität zu Strassburg. Berlin: August Hirschwald, 1908.

In this little pamphlet of fifty pages attention is called to the changes in the tissues caused by the various solutions and steps used in the preparation of histological specimens. Figures are given with respect to changes in porosity, volume, weight, and specific gravity. It should be of interest to the laboratory worker.

Les Eunuques à Travers les Ages, par le Dr. Richard Millant, Paris: Vigot Frères, 1908.

This book of 295 pages, with 20 illustrations by the author, is Volume XIII of a series entitled "Les Perversions Sexuelles." It is written in the sprightly style that stamps the very modern French feuilleton, and as such offers entertaining reading, provided one is willing to accept horrors of brutality and disgusting details of perverse sexuality as entertainment. The author has certainly given much energy to literary research for his subject matter, and presents the results in all the elegance of style of the polished writer. The value of the book to physicians is questionable; criminologists and students of sociology, however, may find some useful points therein.

Etudes sur les Contusions, Déchirures et Ruptures du Rein. Par le Dr. Georges Lardennois, ancien interne des hôpitaux de Paris, prosecteur à la Faculté de Médecine. Paris: Steinheil, 1908.

The object of this monograph of 232 pages, with 22 illustrations, is to present the indications for and against operative interventions in contusions, lacerations, and ruptures of the kidney. These indications are based essentially upon the study of 767 cases reported by other authors, whose contributions Lardennois condenses with remarkable precision. These lead him to conclude that renal contusions are generally benign, that renal ruptures can be produced by slight traumatism, that hemateuria is the sign of renal lesion and hematoma the measure thereof; that a hematoma of considerable size, if untreated, often brings grave mechanical, toxic and infectious complications, which imperil life and are destructive to the kidney. The concomitant lesions render the prognosis grave, but must never discourage the surgeon. The book is well-written, and will prove valuable not only to the urologist, but equally so to the general operator, who has much to do with emergency surgery of the kidney.

Beiträge zur Klinik der Tuberculose. Herausgegeben von Dr. Ludolph Brauer, Professor an der Universität Marburg, Director der Medizinischen Klinik. Band IX, Heft 3. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1908.

This number of the periodical devoted to clinical tuberculosis closes the ninth volume, and consists of six separate articles. Dr. Adolph Schmidt writes of the therapeutic use of pneumothorax and hydrothorax in tuberculosis and bronchiectasis; Dr. Brecke follows with the consideration of tuberculosis of the endothoracic lymph nodes; Benecke and Kürbitz report a case of tuberculosis of the placental site, and Benecke alone a case of air embolism of the greater circulation after an operation upon the lungs. The most important article is that of Roepke, who gives the results of numerous cutaneous, conjunctival and subcutaneous tests for tuberculous infection. Roepke has studied a great deal of material very thoroughly and his article deserves the attention of all who are engaged in testing the values of the new reactions for tuberculosis.

Society Reports.

SIXTH INTERNATIONAL CONGRESS ON TUBERCULOSIS.

Held in Washington, D. C., September 21 to October 12, 1908.

(Special Report to the Medical Record.)

(Concluded from page 652.)

SECTION ON TUBERCULOSIS IN CHILDREN.

Fifth Day—Friday, October 2.

Calmette's Tuberculin Diagnosis.—Dr. L. Emmett Holt of New York said the unfortunate results that had been reported were in sufficient number to warn against using this diagnostic test when other means were available. He cautioned against the error of relying upon these local tests to the exclusion of others.

The Prognosis in Pulmonary Tuberculosis in Children Under Fifteen Years of Age.—Dr. Frank A. Craig of Philadelphia read this paper, which was based upon a study of 193 cases of pulmonary tuberculosis occurring in children, the ages ranging from sixteen months to fourteen years. Among the cases with one or two lobes involved with cavity formation, or with more than two lobes involved, with or without cavity formation, in no instance was the disease "arrested" or "much improved." No patient with a pulse of 80 or less became progressively worse or died, and no patient with a pulse-rate above 120 had the disease "arrested" or "much improved." The respiratory rate also gave valuable information. None of the other factors gave very positive indications. In older children the prognosis was better than in the younger, and the cases treated in the sanatorium did a little better than those treated in the dispensary and hospital. The results in children were better than in adults when the disease was not extensive, but not so good when the disease was advanced.

Hypertrophy of the Lymphoid Tissue; Its Relation to Tuberculosis.—Professor P. Nobecourt and Dr. Leon Tixier of Paris, France, presented this communication, which was based upon investigations of 22 children, whose ages ranged from 31 months to 14 years, with adenoid vegetations and enlarged tonsils. None of them had open pulmonary tuberculosis. Only five of the children were entirely free from tuberculosis. Examination of sections from tonsils and adenoid vegetations in these 22 cases revealed no tuberculous foci, and staining methods failed to show any tubercle bacilli. In only one case did inoculation of the adenoid vegetation produce tuberculosis in the guinea pig, and in this case the child from whom the vegetations were taken was not tuberculous. The authors concluded that there was no evidence that the lymphoidal tissue of the pharynx was the portal of entry of the tuberculosis infection.

The Seashore and Fresh-Air Treatment at Sea Breeze Hospital of Tuberculous Diseases of the Bones, Joints, and Glands in Children.—Dr. John W. Brannan of New York read this paper, illustrating it with lantern slides. Sea Breeze Hospital was the first experimental station for the sea-air treatment of bone and glandular tuberculosis in America, and was established four years ago at Coney Island by the New York Association for Improving the Condition of the Poor. During the four years 136 patients had been under treatment, of whom 68, exactly one-half, were cases of spinal or hip disease, which in 81 per cent. was in an advanced stage at the time of admission to the hospital. Forty-two of the 68 cases had been discharged, and of these 36 per cent. were cured and 19 per cent. improved, making 55 per cent. that were either well or progressing to recovery when they left the hospital. Among the discharged cases were 22 in which the knee or other points were affected Although 80 per cent. were in an advanced stage, 73 per cent. were cured and 13 per cent. were improved. It was demonstrated that to secure the best results in bone and glandular tuberculosis the patients must spend the entire time in the open air, and that the seashore offered especial advantages for outdoor life for children.

A Contribution from Orthopedic Surgery to the Study of Tuberculosis.—Dr. Adoniram B. Judson of New York advanced the proposition that patients affected with tuberculosis would recover and that new cases would not occur if the environment, local and general, was favorable. The argument was brought down to a comparison of two common forms of infection, hip disease and consumption. The statement that the former recovered without treatment except correction of environment was derived from clinical experience and from the literature. It was claimed that if hip disease recovered thus there were reasons in the comparative anatomy and physiology of the lung and the hip for the belief that the same and better results would follow in consumption. A correct environment for consumption was outlined. It was admitted that it was not possible at present to secure for all, the sick and the well, the desired general environment, which included abundant food, innocuous occupation, and sanitary housing, but observations in hip disease indicated that local rest should be secured in consumption by superficial breathing, the cessation of coughing, and the avoidance of exercises which quickened the respiration.

The Possibility of Avoiding Scar Formation in Softened Tuberculosis of the Cervical Glands.—Dr. Willy Meyer of New York believed that by following the rule of making the incisions in the course of the skin-folds of the neck when operating for softened cervical tuberculous adenitis, even long cuts might show very little later on. Still there would be a scar corresponding to the length of the incision made. Bier's hyperemic treatment enabled them to reduce such scars to a minimum if the method was properly carried out with the help of the neckband, as well as suction glasses, especially if combined with open-air treatment, and, of course, if the other means nowadays at their disposal in the treatment of surgical tuberculosis were observed. Dr. Meyer set forth the beneficial effects of the lung suction mask originally designed for the physical treatment of tuberculous pulmonary disease, which also greatly improved the general condition of the blood, a point of the greatest importance in dealing with these usually anemic patients.

Medicinal Treatment of Tuberculosis.—Dr. Abraham Jacobi, president of the Section, in closing, made by request some remarks, as follows: We have heard much of the causes, the pathology, the prognosis of tuberculosis, with much on air, good food, etc., but nothing on the medicinal treatment of tuberculosis. Not a pharmacopœial friend. One need not always give medicines. Many times one sends patients away without medicine, although this may lead to the question: "Doctor, do I owe you anything?" To which he answers: "I have given you the best I have, therefore you owe me something." No disease is uncomplicated. No disease will stand entirely alone, and there is always something to be treated to advantage. For example, constipation in pneumonia, requiring a purgative. Not to give the purgative may be in such cases a dereliction of duty. The purgative not only empties the bowels, it improves the circulation in the intestines, in the liver, in the lungs, and even in the heart. Much has been said of sanatoria, but only for incipient cases. We should have more places for the advanced cases, which can be taken away from thir tenement surroundings and from their families, which will be thus protected from infection. That is being done. Dr. Dixon says that in Pennsylvania he has 500 cases outside cities, and in a few years expects to have 4,000. In New York we are promised (we live on promises in

New York) 5,000 beds for such cases. In such direction lies the hope of limiting infection.

Now, as to the treatment of individual symptoms. Your patient has a cough. That cough keeps him awake at night. Unless you relieve such a cough by an appropriate opiate he may lose more in a single night than he can gain in a fortnight. There is proper medication. There is fever. Long fever is exhausting. It interferes with digestion. Shall we let the fever alone, to get well of itself? It may not do so before the undertaker comes. Fever should be relieved—not let alone—even if you do not believe in medication. Acetanilid should not be given for this purpose. It is a poison, and I have seen quite a number of cases of death from its use. It is always dangerous, even in small doses, and should not be used. Phenacetin should be used for the fever, combined with caffeine, as a rule. For diarrhea many say no medication. Diarrhea does no good. Bismuth will do much for it; opium will do more. If there is hemorrhage with the diarrhea, ergot will do little or no good. Adrenalin subcutaneously will do something. Morphine will do much better. Give enough to allay excitement and keep the patient quiet. Combine with it lead. Not in pharmacopœial doses. I have never seen lead poisoning of my own making. Give with the morphine one or two grains of lead every hour or two for six or eight hours. Then if the patient responds, drop, not the size of the dose, but the frequency. Expectoration—shall we do anything? The usual proprietary medicines will do no good. Use an expectorant, but not a depressant. Ammonia, the carbonate, is sometimes irritating. Liquor ammonii anisatus, 3ssi, every hour or two, is better. Perhaps the best thing is camphor—in powder, pill, or capsule. Give a grain or two every hour or two.

Is there any medicine for the process? None that kills the germs, but some that improve the general condition. Arsenic will do this. If the stomach is disordered, treat that. If the circulation is poor, use digitalis. If digitalis is to be used, see that it is freshly made, of good English leaves, and do not give it in large doses. Guaiacol is preferable to creosote and is cheaper. It is objectionable at first. Five to ten drops can be given three times a day. I always give it with digitalis, strophanthus, or tincture of nux vomica. I often add arsenic to the prescription. Guaiacol carbonate is more easily borne, but is more expensive. Codliver oil is of benefit, but can be given only in winter. In this we give more than oil. It probably contains some substances which affect metabolism like the thyroid.

SECTION ON CLINICAL STUDY AND THERAPY.

Fourth Day, Thursday, October 1.

The Work of the Sanatorium at Bligny.—Drs. L. Landouzy of Paris and L. Guinard of Bligny described the administration of this State sanatorium and noted that the cost of maintenance for each patient was about 70 cents a day; the cost of food alone was 28 to 30 cents a day. The medical results attained were extremely good in the first and second degree cases, but as a rule the advanced cases did not show any marked benefit. Therefore, they considered that the sanatorium should be reserved for the early and curable cases, since the advanced cases cost the State as much for maintenance as the earlier cases and returned no recompense.

Ten Years' Experience in Sanatorium Work.—Professor C. Pannwitz of Berlin read this paper. His experience had shown that the free sanatoria should be constructed not like the general hospitals, but on a different type, having in view not merely the treatment of patients, but their education, so that they could continue their same method of life after returning home. More than 100 free sanatoria, with an average of 100 beds each, were now in operation in Germany. The cost of erecting such a sanatorium need not exceed $1,000 a bed. The rest cure in the sanatorium must be followed by a period during which the convalescent patient follows some light agricultural occupation. The medical treatment should include, beside the general hygenic and dietetic measures, the use of tuberculin administered with the greatest caution to avoid producing any reaction. Recovery was considered from the economic point of view, and not from the pathological. In sanatoria for children the writer laid special stress on the educational feature. The children, too, should be put to work in the gardens after the rest stage. He considered that the sanatorium treatment was a saving of money for the nation.

Ultimate Results of Sanatorium Treatment.—Dr. L. Brown of Saranac Lake considered that the test of the cure lay in the absence of symptoms, and not in the absence of abnormal physical signs. He thought a patient should be considered well if he was able to return to his former life and remain well. In this respect the working class of patients did not do so well as the well-to-do, since they had to return to more strenuous labor. Of the patients discharged from the Adirondacks Sanatorium during the last twenty-three years 41 per cent. were living and engaged in or able to do some work. Of those that were known to be living 87.5 per cent. were still able to work. This included 63 patients who had been discharged more than fifteen years. In regard to the present residence of the old patients the number living in small towns was practically unchanged, while the increase in the health resorts was but little larger than the decrease in the number living in large cities.

Graduated Labor in Pulmonary Tuberculosis.—Dr. M. S. Paterson of Frimley Sanatorium, England, entered a plea for adapting the amount of work allotted to each patient to his ability to stand it. The fever patients were kept in bed and not allowed to make any more movements than was allowed to the cases of typhoid fever. When the temperature fell to normal they were allowed to get up and go to the toilet, and later to sit out of bed, and then the muscular exertion developed by light exercises, and then by walking and labor until the patients would stand a walk of twenty miles without any reaction. A walk of five or six miles was considered an insufficient test of their ability to exercise. He said the slightest exercise by increasing the expansion of the lungs and the blood supply to the lungs increased the toxins in circulation from their point of origin in the tuberculous foci in the lungs, and had the same effect as tuberculin injections, and therefore exercise produced autoinocluation.

The Effects of Exercise on the Opsonic Index of Patients Suffering from Pulmonary Tuberculosis.—Dr. A. C. Inman of London had worked with Dr. Paterson, and believed with him that during the active febrile stage of pulmonary tuberculosis autoinoculations occurred spontaneously. These autoinoculations were evidenced by variations in the tuberculo-opsonic index, which did not occur in nontuberculous subjects. Ninety-five per cent. of the cases investigated at the Brompton Hospital Sanatorium had opsonic indices above normal some time during the day. If the opsonic index showed no variation as the result of hard exercise, whereas before such a variation had been obtained, it was presumptive evidence that the disease was arrested.

The Value of Sanatorium Treatment.—Dr. Arthur Latham of London though that sanatoriums were essential to the successful treatment of pulmonary tuberculosis on a large scale, and to any scheme directed to the eradication of the disease, provided they were used intelligently as an important link in a properly coordinated system of attack. The value of sanatoriums did not meet with universal acceptance because the majority of sanatoriums were

inefficient, acting as hotels, and not as disciplinary schools; because sanatoriums had by some been regarded as sufficient in themselves, which was manifestly not true; because the erection and maintenance of sanatoriums cost so much that it was believed to be impossible to pay for the treatment of the majority of the patients, disproved by the fact that in some of the large factories an insurance fund of one cent a week from all the employees paid the sanatorium expenses of the tuberculous sick from that institution; and because of the difficulty of making arrangements for the maintaining of the family while the breadwinner was at the sanatorium, and in finding suitable work for him on his return home.

The Application of Rest and Exercise in the Treatment of Tuberculosis.—Dr. F. M. Pottenger of Monrovia, California, thought that the functions of the body were best carried on when rest and exercise in suitable proportions could be prescribed. The amount of each must be determined by the natural resisting power of each patient and the pathological condition present.

Rest of the Lung in Pulmonary Tuberculosis.—Dr. Norman Bridge of Los Angeles thought that the tuberculous lung should be kept as still as possible, especially if the disease was unilateral. There was no reason for keeping a tuberculous joint still that did not also apply to the lung; violence to a wound increased scar tissue and would probably increase fibrosis of the lung; violent coughing and lung gymnastics might disseminate the disease; stretching the diseased tissue was liable to injure it. The Bier method of passive congestion doubtless tended to retard disease and help toward recovery, and the lung that was kept still had more passive congestion than the active lung.

Dr. C. T. Williams of London, in discussing this group of papers, asked if the right patients were being sent to the sanatoriums. He thought that only the non-febrile early case ought to go to a sanatorium, and that the advanced cases should go to hospitals for tuberculosis. He thought the portions of the lung that were not involved in tuberculosis needed exercise to make them hypertrophy and compensate for the diseased areas, but such exercise was to be allowed only in the non-febrile cases. He thought there should be a central dispensary for tuberculous cases, from which the early cases should be sent to the sanatoriums, the late cases to the hospitals, and the intermediate cases treated at home.

Dr. Philip of Edinburgh said the question whether a patient should have rest or exercise depended on his general and local condition.

Dr. King of Liberty, N. Y., said he considered a certain rise in temperature following labor as normal, and found that there usually was some such rise, perhaps to 100.6°. If this rise was only temporary, lasting not more than half an hour or so, he did not consider that the degree of labor was contraindicated.

Dr. Minor of Asheville said he disapproved of an excess of rest, considered 99.2° too low a figure to indicate excessive autoinoculation, and held that the fatigue that followed labor was a benefit, if not excessive. He considered the advice of Dr. Norman Bridge was good for advanced cases; but in light cases an attempt should be made to expand first the good lung and later the affected lung.

Dr. Woodcock of Leeds said the sanatorium treatment was usually too short, and a labor colony was needed to complete the good work that had been started. He felt the moral effect of work was so great that all of his patients did something. If too ill to take active exercise, they were given massage, following the temperature, or, rather, the pulse, as a guide.

The Establishment of Dispensaries in Cities and Towns.—Dr. R. W. Philip of Edinburgh considered that a dispensary should be a central institution devoted to the guidance, supervision, and assistance of the tuberculous poor. It should act as an information bureau on all points for those interested in tuberculosis; a clearing house from which all the tuberculous patients who inquired, after a diagnosis had been made, were steered to the proper place for treatment; a center for the supervision of the home treatment of all those remaining at home, and the connecting link which bound together all the undertakings for the prevention of tuberculosis. It should send doctors and nurses to the homes of all its patients, and there, while ostensibly helping the patient that came to the dispensary for aid, they should also find the other cases in the incipient stage which were still early enough to be very hopeful and steer them to the places for best treatment. The dispensary must not stand alone, but be in touch with the public health boards and local authorities.

The Part Played by the Preventorium or Supporting Dispensary in the Social Antituberculosis Fight.—Dr. A. Calmette of Lille said that the preventorium, or antituberculosis supporting dispensary, was essential—an instrument of social preservation against tuberculosis. Its function did not consist in treating patients medically; that was the part of sanatoriums, hospitals, and the medical dispensaries attached to benevolent institutions. Its mission was to seek out, attract, and keep under supervision, by means of active propaganda, those among the poor who were peculiarly exposed to tuberculous infection and those who were already infected. It selected curable patients who were suitable for sanatorium treatment; took charge of children who were menaced or already attacked by the bacillus, placing them in the country or in seaside establishments; sent patients who were dangerous to their surroundings to isolation hospitals; sterilized dwellings; disinfected and cleansed contaminated linen, and distributed sputum cups and antiseptics. It brought about the hygienic education of families through the collaboration of monitors of hygiene, chosen from among the most capable and authoritative men. The sanatorium was exclusively for patients already attacked by disease, but considered curable; but the preventorium extended its benefits not only to patients, but also to their families and their environment. It was a recruiting agency for academic colonies, for sanatoria, and for hospitals, and also was a school for practical hygiene. The work could well be done in part by ex-sanatorium patients. It needed at its head a physician who was also a sociologist.

Dispensary Examinations of Tuberculous Families.—Dr. A. Kayserling of Berlin said that it was not enough to do merely defensive work against the inroads of tuberculosis, but that a distinct offensive work must be done against the tubercle bacillus to protect the uninfected. He urged that the whole family of the tuberculous patient be examined systematically in all cases, physically, by sputum examination, and with tuberculin. While the center of infection was from the open, frank cases of tuberculosis, the fight for the cure must be made among the latent cases, if we wished to prevent the wiping out of families.

The Work of the Chicago Tuberculosis Institute.—Mr. A. M. Wilson of Chicago described this Institute which, beginning in December, 1907, had established seven tuberculosis clinics, which were maintained in conjunction with the large general dispensaries of the city. The Institute supplied a nurse to each clinic, and through its central office coordinated the work of the clinics and prevented duplication.

Dr. Charles Templeman of Dundee said that the dispensaries acted socially as well as medically. That environment and heredity were important in the social and medical development, but that the individual factor was the greatest of all.

Dr. Stafford of Ireland said that he considered the dispensary, as outlined by Dr. Philip, the most efficacious of all plans for the extermination of tuberculosis, for nothing

but the coordinated action of all the antituberculous modes of combat would be efficient.

Dr. Krause of Jena said that in the dispensary work he cut down expenses by having the senior medical students do the medical work, and thus trained them, aroused their interest, and get plenty of assistance at the minimum cost.

Dr. Minor of Asheville said that the State care of the sick must always be careful not to undermine the morale of the patients. That it was better to have the patients die uncured but independent, rather than have them get well to live forever at the expense of the State.

Comparative Value of the Dispensary and Sanatorium Treatment.—Professor Fritz Egger of Basle brought out the point that both were useful and needed, as their aims were different. The dispensary did not give treatment. The sanatorium results had not been as good as was hoped for, because they were not so permanent. The dispensaries had larger early mortality, but later on about the same mortality as the sanatoriums, because the sanatorium patients had not learned to work under home conditions. The tuberculous patients in the first stage, and earlier, needed only hygienic treatment at home, and need not go to the sanatoriums. The dispensary should also take cars of the patients going out from the sanatoria.

The Care of Patients in the Advanced Stages of Pulmonary Tuberculosis.—Dr. Meyer of Berlin said that since the advanced cases of tuberculosis were a distinct source of the spread of tuberculosis, particularly under unfavorable living conditions, measures should be taken to limit the constant advent of newly infected individuals. The isolation of the patients, therefore, was important. The institutions for isolating patients should be so constructed as not only to guard against infection, but also to hold out prospect of recovery to the patients and make them feel that they could get well at the sanatorium, but not at home. They should not differ so widely from other hospitals as to create a prejudice against them.

Prof. von Leube of Germany said that since it was impossible so far to immunize the healthy, we could hope for extermination of the disease only by destruction of the bacilli causing the disease. This could be done by preventing carriers from coming in contact with the healthy and by destruction of the sputum. Sanatoria offered the hope of cure for the second stage cases and improvement for some of the third stage cases.

Fifth Day—Friday, October 2.

Day Camps for Consumptives.—Dr. David Townsend of Boston called attention to the lack of provision that had been made until recently for the type of case which was unsuitable for the sanatorium of incipient cases and the homes for the advanced cases. To provide for these, in 1905 the Boston Association for the Relief and Control of Tuberculosis operated the first camp in this country near Boston during the summer months. The equipment consisted of a kitchen shack, an administration shack, a dining tent, and several smaller tents. Paper bags and crepe paper napkins were used for sputum and burned at night. The patients had two lunches and a dinner each day. They came at 9:30 A. M., and returned home between five and six in the evening. They spent the day in reclining chairs at rest, or in moderate amusement under the direction of a nurse and physician. The chief aim of the camp was educational. Lectures on various health topics were given each season.

Night Camps.—Dr. W. C. White of Pittsburg said there were many tuberculous subjects who were working, conscious of their lesion, but from their existing circumstances compelled to work, or not working but able to work four to eight hours daily. Among these there were many who needed supervision, and many who could not have proper care in their existing home or boarding house. For these the reasonable and most valuable scheme was the night camp, where they could be supervised and taught and cared for during the night hours after work, in the evening and before going to work in the morning, and given the benefits of fresh air and hygiene all of the time that they were not employed.

The Treatment of Tuberculosis in Other Places Than Sanatoria.—Dr. Charles L. Minor of Asheville thought the hygienic and dietetic treatment which are now universally recognized as a fundamental part of any and all rational treatment of tuberculosis could be applied as well outside of sanatoria as in. The essential features of home treatment were careful personal medical oversight, strict discipline and close supervision, thorough instruction, systematic and hygienic arrangement of the patient's life, example of other patients, nursing, proper housing and feeding, and suitable climatic conditions.

Dr. T. D. Coleman of Augusta, Ga., in a paper on the same subject, said this was a question of the greatest importance, because the greater number of tuberculous patients must be treated in their homes. He thought that as rigid discipline and as intelligent medical oversight might be had in the home as in the sanatorium, and that all of the indications for treatment might be carried out equally to the advantage of the patient.

Economic Housing of Consumptives, with Especial Reference to the Southwest.—Dr. P. M. Carrington of Fort Stanton dealt with the large number of consumptives attracted by the fame of climate resort in the Southwest. As a result of education regarding tuberculosis, phthisiophobia has developed among the people of that region, making it difficult for avowed consumptives to obtain accommodations in hotels and boarding houses. So that now it was necessary to teach prevention as well as communicability of the disease. The most recent tent dwelling was the tent house, which was inexpensive, perhaps $150 per bed, or even as low as $60 if no toilet was supplied. These tent houses could be grouped conveniently, were isolated, had a small fire risk, and were adaptable to any climate.

Sanatoria for the Well-to-Do.—Drs. C. F. Gardiner and A. H. Swan of Colorado Springs and Herbert M. King of Liberty, N. Y., presented this communication. In both rich and poor the principles of treatment were the same, but the methods of application differed. In the sanatoria for the rich the arrangement and construction must be such as to afford the greatest privacy and personal comfort consistent with the sanatorium methods, so that the cottage plan was preferable. Location, environment, and climatic features were greater desiderata. The application of carefully graded physical exercises was very much more difficult in the leisure class. The dietetic management also was more difficult, and the psychic features were the worst of all.

The Value of X-Ray Examinations in the Diagnosis of Early Tuberculosis.—Dr. Paul Krause of Jena said that after ten years of use he had come to the conclusion that the diagnostic value of the *x*-ray was very great. A fluoroscopic examination should be made in an absolutely black room, the tube being kept guarded in a lead-lined box. There should be noted the comparative density of the two apices, the enlargement of the glands at the root of the lung, the calcification of the first rib. And the examination should be repeated after several weeks. He could learn more from the fluoroscope than by the auscultatory percussion method. Plates were taken to give greater detail.

Tuberculosis in the Hospitals for the Insane.—Dr. Richard H. Hutchings of Ogdensburg said the death rate of the insane from tuberculosis was 16.6 per cent., as compared with 10 per cent. among the general population. The frequency of the disease among asylum patients depended to some extent upon the environment of the patients prior to admission and the conditions in the hospital.

such as overcrowding and poor ventilation. Measures for the prevention of tuberculosis included, beside the ordinary measures for cleanliness, a more critical examination of new patients, employing tuberculin if necessary, isolation of the infected persons, reduction of overcrowding, free ventilation, daily exercise and outdoor employment for both men and women, and sterilizing all garments and bedding before such were used by a second person.

The Indications and Contraindications of High Altitudes.—Dr. Exchaquet of Leysin said all patients able to cope with the cold air should be given the advantages of the high altitude. The only true contraindications were in late cases with reduced resistance and the cases of weak heart with rapid pulse. Asthma and emphysema might be contraindications if they were very marked. The tendency to congestion of the lung offered no contraindication. Hemorrhages at high altitudes he had seen very rarely, even in those who had been having hemorrhages before coming to him. Fever was not a contraindication, but rather the reverse, as the fever usually subsided in the higher levels. Laryngeal tuberculosis might be irritated at first by the dry air, but the ultimate result was very beneficial.

Mexico's Central High Plateau as Sanitary Stations for Tuberculosis.—Dr. E. Liceaga of Mexico thought that the reason more attention and value had not been given to altitude as a factor in the treatment of tuberculosis was on account of the low altitudes considered. Higher altitudes affected the growth of vegetation, minor organisms, and so reasonably might be expected to affect the tubercle bacillus, and, as a matter of fact, the severity of tuberculosis was in proportion to the altitude at which the group of patients lived. Yellow fever occurred only at altitudes below the level of 3,000 feet, and typhus fever was also affected by altitude. The City of Mexico was at a level of nearly 7,000 feet, and the death rate from tuberculosis was less than that of any forty cities of lower level in Europe and America that he cited. The climate, too, was most satisfactory, the range of temperature being very slight all the year through.

The Relation of High Altitudes to Tuberculosis.—Dr. V. Lopez of Mexico made the point that the high altitude decreased the blood pressure, thus avoiding the tendency to hemorrhage and increased the respiratory capacity and expansion of the lungs. The dryness of the air tended to decrease the exudation from the bronchi.

The Mercurial Treatment of Tuberculosis.—Dr. Wright of the U. S. Navy noted the pathological similarity of tuberculosis and syphilis, both being in the class of chronic granulomata. He found 35 per cent. of the cases improved under mercurial treatment. During the last year he had had opportunity to test this treatment in a series of tuberculous patients at one of the Western stations, and the mortality from tuberculosis had fallen from 11 per cent. in the first quarter to 4 per cent. in the second quarter, and 0.95 per cent. in this last quarter. Therefore, he considered mercury a strong antituberculous remedy, if not a specific.

Dr. Liceaga of Mexico said that he had been using mercury in tuberculosis for forty years, and from the excellent results of his clinical experience knew it to be distinctly beneficial. He used potassium iodide, also, but considered it dangerous in cases of hemorrhage.

Recognition of Pure Pneumothorax, without Exudate, in Pulmonary Tuberculosis.—Dr. Herman von Schroeter of Vienna said the objective symptoms of pneumothorax might be so indistinct that it was impossible to make a certain diagnosis without the spirometer or the radioscope. The spirometer showed a sudden decrease in lung capacity by just one-half; and the radioscope showed the absence of the lung from its normal place.

The Coagulability of the Blood in Pulmonary Tuberculosis.—Dr. Meyer Solis-Cohen of Philadelphia said the average time of coagulation was for normal people eight and two-third minutes, and for tuberculous patients five and one-sixth minutes. The coagulation time was practically the same for all stages of the disease, and was not affected by atmospheric conditions. In three cases tested before and after a hemorrhage the time before was about seven minutes and after about four minutes. Diarrhea and menstruation did not affect coagulation time. Pleural effusion, if serous, seemed to have no effect, but when purulent increased coagulation time. The efforts of calcium salts were not conclusive.

Dr. Woodcock of Leeds had found the coagulability decreased after calcium salts continued for a prolonged period.

The Improvement of Tuberculosis of the Lung Under the Influence of Artificial Pneumothorax.—Dr. Spengler of Davos considered the operation desirable in one-sided lesions, or in double lesions if one side was inactive. He followed the method of Murphy in the production of the pneumothorax.

Condition of the Teeth in Tuberculosis in Relation to Prognosis.—Dr. B. S. Paschal of Seattle considered the cross ridging and malformation of the teeth from interference with tooth formation before eruption as due practically to either syphilis or tuberculosis. These inoculations of childhood were the cause of later immunity, but repeated infection in childhood might cause an adaptation of the bacillus and the child to each other so that they could live together without any active disease being evident. If the child did not have the early inoculations, but first came in contact with the tubercle bacillus at a later date, his powers of resistance were diminished and the disease germ gained a better hold. Hence if the teeth were hard and perfect the infection would be greater.

SECTION OF SURGERY AND ORTHOPEDICS.

Fifth Day—Friday, October 2.

Tuberculosis of the Vas, Epididymis, and Testicle.—Dr. John B. Walker of New York read this paper. This condition was rare in infancy, and most common between the ages of 20 and 30. It usually occurred as a primary tuberculosis of the epididymis, and was not associated with pulmonary tuberculosis. Gonorrheal epididymitis was recognized as a causative agent, various observers giving it as a factor in from 5 to 35 per cent. of cases. Trauma was also a predisposing factor. The bacilli gained entrance most frequently through the respiratory or the gastro-intestinal tract, lodging in the mediastinal or intestinal lymphatic glands, whence they were carried through the circulation to the epididymis. The onset was generally gradual; there was a feeling of weight and discomfort in the testis, followed by tenderness, and later a dull, aching pain. A urethral discharge was generally present, at first slight frequency of urination; later, tenesmus; the urine contained a small amount of pus, blood, and mucus. The disease had to be differentiated from gonorrheal epdidymitis, syphilis, and neoplasms. The prognosis varied with the extent of the disease. Some cases remained local a long time. Removal of the testis often effected a cure, whether or not the prostate and seminal vesicles were affected. The general treatment was the same as in other forms of tuberculosis. Abscesses should be incised. When cases were recognized early, epididymectomy was the operation of choice. It should be performed in all cases of localized tuberculosis of the epididymis. It was important to preserve the testis wherever possible on account of its internal secretion. Following epididymectomy the testicle did not atrophy, and the patient retained his sexual desire. Orchidectomy should be limited to cases of extensive disease of the testis. In many cases even where the prostate and seminal vesicles were affected, epididymectomy or orchidectomy would be followed by a subsidence of the prostatic and vesicular symptoms. Slight tuberculosis of the testicle might be depended upon to heal

spontaneously after removal of the epididymis. Castration was especially objectionable when both testes were involved. At least a portion of one testicle should be left. Serious involvement of distant parts did not contraindicate operation, since it could be done under local anesthesia.

Dr. William E. Lower of Cleveland, O., said that some claimed the infection of the epididymis and testicle was always a descending one, others that it was always primarily in the epididymis, the infection spreading in the direction of the normal secretions. The same difference existed as to the proper method of treatment. Some insisted upon removal of the testis, epididymis, vas, prostate, and seminal vesicles; others advised the removal only of the diseased epididymis or testicle. Still another class advised a "let alone" method, or the use of some sort of injection treatment. The speaker believed that the disease was practically always of hematogenous origin, and that the infection ascended along the vas in the direction of the normal secretion. As to treatment, formerly he did a very radical operation, but now he simply removed the more diseased parts, and his results were better.

Surgical Tuberculosis.—Dr. E. H. Bradford of Boston read this paper. The treatment of tuberculosis was dependent for its ultimate result upon establishing an immunity which would protect from further tuberculous invasion. When the tissues invaded were placed under suitable conditions healing took place and the affected tissues became cicatrized. The detritus of diseased tissues was either thrown off or became encapsulated. In tissues within the reach of surgical interference the surgeon was to decide whether the healing process could be hastened by removing the affected tissue or the detritus. This depended upon the tissues affected and their anatomical situation. These considerations were particularly important in bone tuberculosis and tuberculosis of the joints, for the reason that bone was a tissue that cicatrized slowly, and the articulations were especially exposed to injury which was unfavorable to the healing of the tissues affected by tuberculosis. In joint tuberculosis it was especially important to see that the tissues were protected from trauma. The treatment of surgical tuberculosis consisted in operative interference and the promotion of healing by protecting the tissues, in addition to furnishing such measures as were useful in combating tuberculosis in general.

The Prevention, Diagnosis and Surgical Treatment of Tuberculous Sinuses and Abscess Cavities.—Dr. Emil G. Beck of Chicago read this paper. A 33 per cent. bismuth-vaselin paste was first used in connection with the *x*-ray, in diagnosing the extent of tuberculous and other sinuses. This led to the discovery that this paste had a marked curative effect upon such sinuses. On January 15, 1908, Dr. Beck had reported 14 cases in which the paste had been used. Since then he had collected 178 cases in which it had been used. He presented a table showing the results in 192 cases. Of these healing occurred in 123, or 64 per cent.; improvement in 55, or 28 per cent.; no improvement in 11, 6 per cent.; death in 3, or 1.5 per cent. Of these cases, 146 were tuberculous, 22 nontuberculous, and 24 doubtful. Fistulous tracts might be prevented by opening the pointing cold abscess by an incision ¾ cm. in length, evacuating the pus, and at once refilling the abscess cavity with a 10 per cent. bismuth-vaselin paste, and not sealing the opening. This prevented secondary infection, the danger of which formerly contraindicated the incision of tuberculous abscesses.

Fresh Air Combined with Hyperemic Treatment in the Management of Complicated Surgical Bone Tuberculosis in Adults.—Dr. Willy Meyer of New York read this paper. The beneficial influence of fresh air in surgical bone tuberculosis in children was generally recognized; not so in adults. In the latter, radical operation had been the usual treatment up to date, and would probably continue so wherever the saving of time was a factor to be considered, or where sufficient means were not at hand. The histories of three cases of complicated bone tuberculosis in adults were given to demonstrate how much could be accomplished even in usually intractable cases, especially if combined with proper and faithful hyperemic treatment in its various forms. The plea was made to set aside in the sanatoria now designed for patients suffering from pulmonary tuberculosis at least two wards, male and female, for the treatment of adult cases of surgical bone tuberculosis which, for various reasons, could not or would not be subjected to operation. Of course, the attending doctors and nurses of such wards should fully master the details of hyperemic treatment.

How the State of Minnesota Cares for Its Indigent Children Suffering from Tuberculosis of the Bones and Joints.—Dr. Arthur J. Gillette of St. Paul, Minn., read this paper. In 1897 the Legislature of the State of Minnesota first appropriated money for the State care of indigent crippled and deformed children. There being no precedent, the State was reluctant to take such a step. Since 1897 a number of States had made similar appropriations. At the present time it ought not to be a difficult matter to secure money from every State in the Union to treat and educate this class of sufferers. It was of special importance, for it was found that about three-fourths of these crippled and deformed children were suffering from tuberculosis of the bones and joints. Many of them had complications of tuberculosis of the lung, intestines, etc., and a very large percentage of them had abscesses and running sores, which not only contained bacilli of tuberculosis, but other infectious microorganisms. Many of these children attended public school, and no provision whatever was made to protect the well children in the schoolroom, or prevent contagion in their own families. It took at times a number of years to cure a child suffering from tuberculosis of the bones and joints, and the educational feature was a very important one. They must be educated, and they should have special instruction along a line of work which would be useful later, that they might be self-supporting. With the exception of a few States and a few large cities, there was no provision to prevent contagion, or treat persons suffering from tuberculosis of the bones and joints.

Tuberculosis of the Kidney.—Dr. Arthur Dean Bevan of Chicago read this paper. Infection practically always occurred through the blood. Though the kidney might be the first organ to give evidence of disease, tuberculosis there was usually secondary to some obscure lymphatic lesion. Ninety per cent. of cases were unilateral in the beginning. Later the disease might extend to other organs or the opposite kidney. There should be a distinct line drawn between urinary tuberculosis and genital tuberculosis. Urinary tuberculosis began in the kidney and extended, in the direction of the flow of the urine, to the ureter, bladder, etc., while genital tuberculosis began in the epididymis and extended to the vas, prostate, seminal vesicles, etc. Early diagnosis was the most important thing, and depended upon finding tubercle bacilli in the urine. A twenty-four hour specimen should be examined. The smegma bacillus should be excluded by obtaining the urine by catheter and by decolorizing with alcohol. Cystoscopy might show redness, swelling, and ulceration of the mouth of the ureter on the affected side. The ureters should be catheterized, and the freezing point of the blood determined. If it was normal, 0.55 to 0.57, or even as low as 0.59, nephrectomy could be safely done. The *x*-ray would differentiate from calculus. There were three methods of treatment, general hygienic, tuberculin, and surgical. The hygienic treatment was of great importance. The value of tuberculin treatment had not been determined. In unilateral tuberculosis nephrectomy was the operation of choice. In bilateral cases the treatment should be hygienic; possibly tuberculin might be used; and certain palliative operative procedures, as nephrotomy and drainage, as might be required.

Iodine Therapy in Surgical Tuberculosis.—Dr. Cesidio F. Gualano of Naples recommended the use of a 5 per cent. solution of iodine in an artificial serum with guaiacol. This might be injected hypodermically, intramuscularly, or intravenously. In most cases hypodermic injection was painful, and therefore intramuscular injection was preferred. The dose varied according to the age of the patient and the duration and intensity of the tuberculous process. The daily dose of one centigram might be increased to three, five, and more. In the past ten years he had cured thirty cases of surgical tuberculosis in this way. The histories of seven cases were given in detail. Other papers read were: "Treatment of Surgical Tuberculosis by High Altitudes and Sunlight," by Dr. Rollier of Leysin, Switzerland. "Tuberculosis of the Muscles, Fasciæ, and Tendons," by Dr. James F. Mitchell of Washington, D. C. "Tuberculosis of the Gall-Bladder, Pancreas, Stomach, and Liver," by Dr. L. W. Hotchkiss of New York. "Acute Forms of Abdominal Tuberculosis," by Dr. Daniel Eisendrath of Chicago. "Rational Spinal Support," by Dr. Henry W. Frauenthal of New York.

SECTION ON HYGIENIC, SOCIAL, INDUSTRIAL, AND ECONOMIC ASPECTS OF TUBERCULOSIS.

First Day—Tuesday, September 29.

Mr. Edward T. Devine of New York, President, in the Chair.

President's Address.—Mr. Edward T. Devine said that this was the first time that a section on these subjects had met in connection with a national tuberculosis association. The field they expected to cover was one that had been neglected by health boards and physicians, or if not neglected one that was considered as lying outside their province. The main work of this section should be the endeavor to secure immunity from tuberculosis by the improvement of the resisting powers of the individual by raising the standard of hygiene and sanitary environment. It was their work to educate the people and to force upon society its responsibility in respect to these conditions.

Economic Aspects of Tuberculosis.—This was the topic for discussion at this session.

The Cost of Tuberculosis.—Professor Irving Fisher, Yale University, said that the present death rate from tuberculosis would cause the death of 5,000,000 now living. The average age of death for the males would be 37.6 years; for females, 33.4 years, and the "expectation of life" lost was at least twenty-four years, of which at least 17 would fall in the working period. The average period of disability preceding death from tuberculosis exceeded three years, of which the latter half was the period of total disability. The money cost of tuberculosis, including capitalized earning power lost by death, exceeded $8,000 per death. The total cost in the United States exceeded $1,100,000,000. About two-fifths of this expense fell on others than the consumptive. The cost of treating patients at sanatoria was repaid many times over in lengthened working lives. He considered the erection of isolation hospitals for incurables as the most profitable method at present of reducing the cost of tuberculosis.

The Economic Loss to New York State in 1907 from Tuberculosis.—Professor Walter F. Wilcox, Cornell University, consulting statistician, New York State Department of Health, said that the economic loss to a community from tuberculosis was made up of several elements: First, the loss resulting from the diminished earnings and increased expense during the period of the onset of the disease and the death of the patient; secondly, the loss of net earnings between the actual date of death and the time when death would probably have occurred had the person not been attacked by tuberculosis; thirdly, the monetary loss to farmers and dairymen each year resulting from bovine tuberculosis. In New York State the first element had been roughly estimated at $11,184,750. It was probable that the prospective earnings of the 16,570 persons who died of tuberculosis in New York State in 1907 was $52,251,757. The annual loss of cattle must have been at least $1,500,000, and the total loss in money was not less than $65,000,000 a year. An infant would have its expectation of life at birth increased by about two and a half years if tuberculosis were to disappear and other conditions remain unchanged.

The Burden on Individuals and Families.—Mr. Sherman C. Kingsley, superintendent Chicago Relief and Aid Society, limited his remarks to the consideration of those in moderate circumstances, working people earning from $9.00 to $18.00 per week. This income left no margin for emergencies. They disregarded their physical ailments, and tuberculosis was, as a rule, far advanced when discovered among these people. This disease cut off the income and increased the necessary expenses. Such families in our large cities lived in an average of about three and a half rooms. The condition of twelve families where the father had tuberculosis showed a decrease of an average income from $12.66 per week before the disease to $4.16 per week after the man had been forced to give up work. In a recent examination of 150 families twenty-five to thirty per cent. of all the children in these families showed signs of infection. This disease forced children out of school at the earliest possible age, exhausted family recources and vitality and fastened itself on the weakened member. Some obvious needs suggested were more hospitals for advanced cases, more sanatoria for incipient cases, more funds to save fathers and mothers still in the incipient stages, a wide increase in tuberculosis clinics, day camps, and church classes as adjuncts to the home care of patients.

The Relation Between Tuberculosis and Mental Defect.—Dr. Martin W. Barr, chief physician to the Pennsylvania Training School for Feeble Minded Children, Elwin, Penna., asserted that tuberculosis was a potent factor in the production of mental degeneracy, and that this fact was confirmed in a comparison of two etiological tables compiled from the studies of over six thousand cases made, one in England and one in America. This opinion was further verified in the statistics of various asylums where family history revealed tuberculosis trouble as cause, either singly or associated with other fateful heredities. The prudential motives governing the isolation of tuberculosis in institutions, and the equal necessity for the sequestration and perpetual safe-guarding of imbeciles, was emphasized in this connection; as incapable of judgment, ignorant or regardless of consequences, these unfortunates could not but prove a double menace to society as active agents, however involuntary, in the dissemination or procreation of tuberculosis. That the tendency of both of these forms of degeneration was to deorganize and to lower the entire tone of the whole system as to minimize resisting power was patent to the most casual observer. Naturally, any close association of such conditions must insure to its victims a certainty of one evil or the other, or, as was frequently the case, a mingling of the two.

Effective Control in Small Towns and Rural Communities.—Mr. Homer Folks, secretary State Charities Aid Association of New York, described the work of this organization in New York State.

Standardization of Investigations.—Professor John R. Commons, University of Wisconsin, Madison, characterized tuberculosis as par excellence the disease of social environment. This disease was driving labor bureaus and health boards into cooperation, but this cooperation was not effective unless we had uniformity of nomenclature of diseases and occupations. These units could be standardized by adopting the score card used in grading live stock,

grains and agricultural products. The score card analyzed the several points of an animal and gave a value or weight to each point and the total gave the grade compared with the standard. The adoption of such a method would do as much for sociology as the standardization of units had done for the different branches of physical and chemical engineering.

The Influence of Overwork and Nervous Strain in Tuberculosis.—Dr. George Dock, of Ann Arbor, Mich., said that in order to understand why and how overwork and nervous strain were harmful they must understand: (a) the general nature of tuberculosis, (b) its effect on the body, (c) the possible modifying influences of overwork and nervous strain on these processes. The most frequent and characteristic action of tuberculosis was its wasting effect upon the body. Another constant feature was loss of strength. Many persons were able to keep up a fair degree of work notwithstanding the loss of strength. Stadler found among 670 dispensary patients 55.1 per cent. at work a year after the disease was discovered, and 46.6 per cent. after two years. The mind was also often affected, so that we saw morbid irritability and depression or sometimes their opposites, exaggerated hopefulness. Loss of memory, and their usual tendency to mental fatigue, were often added to other psychic changes. It was obvious that the tuberculous patient, at the best, was in the condition of a person overworking. Not infrequently he was overworking with insufficient food. The effects of overwork and infection on the previously healthy body had been known for some time, and it had been found by experiment that a lot of animals overworked on treadmills succumbed to pathogenic germs that were not so dangerous for control animals not made to work. Overworked persons or animals were much more susceptible to infection than others. The rôle of nervous strain could not be so easily demonstrated by experiment, but they knew from too abundant observations how overwork and nervous strain, especially in the form of worry and care, were combined in the tuberculous patient. This was important not only in the production of disease but still more so in the course of the disease. The latter they knew was usually chronic, with a strong tendency to recovery under favorable circumstances, but these the average tuberculous patient could not acquire. If the partly healed patient could not earn an income adequate to his needs his home conditions and diet became unsatisfactory and relapse followed. From the philanthropic standpoint it was needful to advise or rearrange methods of securing proper occupation for the partly healed tuberculous patient. We must recognize that the present methods offer a hygienic and financial danger to the whole population. To meet this need would require a great increase in our hospital facilities. It was also necessary that the family be cared for if the tuberculous patient was to be spared the effects of nervous strain. It might seem to some that these things did not come within the province of the tuberculosis problem, but the problem was social as well as medical, and society would have to assist in solving it.

The Cash Value of Factory Ventilation.—Professor C. E. A. Winslow, Massachusetts School of Technology, reported a study of the effect of improved ventilation upon the efficiency of factory operatives. The plan adopted was to find instances where marked improvement in ventilation was made without other material differences and to study statistics of attendance before and afterward. In one instance the average percentages of absences among 60 girls was cut in half. In three months the saving amounted to $195 for the employer, while but $75 was expended to secure proper ventilation. This might be an exceptional case, but the fact remained that improved sanitary conditions did bring a tangible result, sometimes a large one in proportion to the cost.

Tuberculosis and Working Conditions.—Mr. Frank Duffy, general secretary United Brotherhood of Carpenters and Joiners of America, stated that the records in the Death Claim Department of this organization showed that 37.3 per cent. of their members died of consumption during the past two years, and of this number over 50 per cent. were employed in mills, factories, etc., or had insufficient nourishment, or the disease was brought about by exposure, bringing on pneumonia, which later developed into tuberculosis. He assumed that consumption was a condition and not a disease, because primarily it was the condition which caused the disease.

The Economic Aspects of Tuberculosis in Milwaukee.—Dr. Thomas W. B. Crafer of Milwaukee stated that the death rate from tuberculosis in this city was much greater among the foreign population than among the native. The occupations which showed the highest death rates were those of unskilled laborers, factory employees, domestic and shop clerks in the order named. Of housewives who died of tuberculosis who had not worked in factories nor as domestics the average age at death was 34.9 years, while the average age at death of those who had worked in industries was but 27 years. Tuberculosis had been most fatal in the more congested parts of the city. It was a conservative estimate that 40 per cent. of all the families in this city having tuberculous members were absolutely incapable of affording proper conditions of housing, freedom from worry, nourishing food, and medical attendance.

Pulmonary Tuberculosis Among Printers.—Dr. James Alexander Miller of New York presented this paper, in which he concluded that tuberculosis was very prevalent among printers, and that this was due to unfavorable shop conditions, especially poor ventilation, overcrowding, dust, dirt, promiscuous spitting, and poor lighting. Secondly, it was due to the irregular habits of the printers themselves, especially alcoholism, careless habits of eating, needless exposure to drafts and insufficient outdoor exercise.

Legitimate Exercise of Police Power for the Protection of Health.—Dr. Henry B. Favill, Chicago, in behalf of the American Association for labor legislation, read his paper and concluded as follows: 1. Measures of regulation of industrial affairs in behalf of the laborers inevitably carried with them much of the controversy between capital and labor, and were difficult to institute. 2. It was becoming generally accepted that health was the essential factor in productiveness and prosperity, and hence in the advancement of civilization. It followed, therefore, that the State in pursuit of its primary function, must take cognizance of fundamental necessities. 3. The conditions under which labor shall be performed as related to health became matters of primary interest to the State, and upon that basis should be the subjects of decisive, mandatory legislation. 4. Inasmuch as all legislation was subject to judicial review as to what was constitutional, regard should be paid to the trend of judicial opinion. Thus far three things appeared as important: (*a*) That the subject should be clearly a health proposition. (*b*) That it be general and not class legislation. (*c*) That the contention be supported by reliable data. 5. Tuberculosis was the most imperative subject before them. Data upon this subject were meager and must be acquired through systematic research. To accomplish this, much "police" co-operation would be necessary. 6. Broadly speaking the reeducation of the masses as to the value of fresh air and the practicability of being subjected to it was a colossal undertaking, but of fundamental importance. 7. The importance of fresh air as a physiological stimulus, leading to individual vigor, must be emphasized. Its value as an atmospheric purifier was important though decidedly secondary. 8. The readjustment of industrial conditions to an adequate supply and distribution of fresh air was the one great thing to accomplish. The difficulties were so great as to be appal-

ling. The necessities were so clear as to be imperative. 9. Sanitarians and sociologists must combine to accomplish this reform. As it now appeared, nothing short of the broadest exercise of police jurisdiction would be effective. Subordinate health law naturally followed.

The Legitimate Exercise of the Police Power in Protecting the Life and Health of Employees.—Hon. David J. Brewer, associate justice of United States Supreme Court, discussed this subject. He said that it was the function of the police power to regulate the relations of one individual to another. The police power was directly for the individual, and only indirectly benefited that state. All the powers of this state had limitations. Taxation was only permitted for public purposes, and when one came to the police power the courts had said that when exercised by a municipality the ordinance must be reasonable; the courts struck down the ordinance if it was not reasonable. Each lower power had to act reasonably or a higher one stepped in to protect the people. The police power might inquire if the employer provided safe machinery, safe structure, and safe conditions for the employees, but the master did not guarantee absolute safety, only reasonable safety. The employer owes safe conditions for labor to the employee, and could be compelled by law to furnish them. The transportation companies were compelled to furnish safe conditions for their employees, and also for those who used the transportation. If the employee was worked beyond a certain point he was unfit to do his part in affording safety to those transported. In certain kinds of employment involving special risks to the employee the State could come in and limit the number of hours that the employee could work; but where there was no special risk the courts held that an able-bodied man could contract for as many hours' work as he wished. This was right under principles that guaranteed to every one the right to life, liberty, and the pursuit of happiness. The Oregon case which had tested the validity of the law limiting the number of hours that a woman was permitted to work had been decided rightly, because it was for the welfare of the race that the woman should not be overworked.

The Problem of Tuberculosis in Cuba.—Dr. J. Jacobsen, president of the Cuban League Against Tuberculosis, said that the problem of tuberculosis was the same generally in Cuba as in any other country, and the disease there was due to the same causes and presented the same clinical picture. Yet the presence of a great many tobacco manufactories gave a certain special character to the problem in Cuba, as these were doubtless the great source of tuberculosis. Another special character in Cuba, was that hitherto, at least, the private societies, the League among them, and private agencies had lacked the necessary resources to undertake prophylactic measures, and in order to be really effective they should be supported by and be under the control of the Government. On the other hand, the geographical conditions of the island easily permitted of accurate and extensive statistical work, which was a fundamental basis in the problem of tuberculosis. The author pointed out its importance and proposed, among other suggestions, a strong organization for the collection of statistics in Cuba. He referred to the hospitals, sanatoria, and dispensaries, and pled for a speedy organization of dispensaries in the provinces, at least one in every large city of the island. He concluded that the problem of tuberculosis affected all interests, and that the League for the Prevention of Tuberculosis had pointed out the general lines for the organization of public services against tuberculosis.

Prevalence and Control of Tuberculosis in the Philippine Islands.—Dr. Victor G. Heiser, chief quarantine officer and director of health of the Philippine Islands, was of the opinion that in that country intestinal parasites played an important part as regards the mortality and morbidity of tuberculosis. In 1904 tuberculosis was responsible for over 50 per cent. of the deaths in a prison whose inmates numbered 3,000. Since December 1, 1904, all tuberculous patients were isolated. During 1905 there was an increase in the number of deaths from tuberculosis, although there were fewer new cases. Sanitary regulations had been put into effect, and the death rate fell to 75 per thousand population. Eighty-four per cent. of these were found to be infected with intestinal parasites. When measures were instituted to eliminate these parasites the death rate fell to less than 20 per thousand of population. The greatest mortality from tuberculosis in the Philippines occurred in June and October, the wet months. About the same percentages prevailed among the general population as it did in the prison. During the past year the death rate from tuberculosis had fallen from 50 per cent. of the entire death rate to 13 per cent. The campaign against tuberculosis in the Philippines was hampered by the primitive mode of life of the natives. Two years ago an active campaign of education was begun. Overcrowding was prohibited by law. Land greed had increased the overcrowding since Manilla had come into the possession of the United States. He was convinced, however, that the elimination of the hook work would vastly aid in the solution of the tuberculosis problem in the Philippine Islands.

Work Done by the International Antituberculosis Association.—Dr. Helm of Berlin read this paper and concluded as follows: (1) The International Association against tuberculosis developed from the International Centra Bureau for the prevention of tuberculosis, which was founded in Berlin in 1902. It included all the countries of the world in which a systematic warfare against tuberculosis was carried on. At the present time the number included 22 states. It contained among its members the most eminent authorities on tuberculosis, and on practical methods of combating the disease in those countries; physicians, investigators, public officials, sociologists and philanthropists, who are active, honorary, or corresponding members. The total membership was about 800. (2) The object of the Association was to encourage those phases of the fight against tuberculosis which requires the cooperation of all the countries in the world. These included comparative studies of law and police regulations in regard to tuberculosis; notification, disinfection, segregation of advanced cases, with the taking charge of consumptives by insurance institutions, occupational hygiene, the care of the home, etc. The introduction of uniform methods of gathering tuberculosis statistics, investigations in regard to the spread of tuberculosis to other countries and races, and finally the scientific inquiry into the causes of tuberculosis (infection paths, heredity and predisposition, disposition, occasional causes), and of the methods of treatment. (3) The means by which these problems were to be solved were, in the first place, the annual conferences of the Association (usually a session of the Inner Council, and every third year a session of the General Council), where scientific and practical questions in regard to which circular letters may have been sent out were discussed. The publication of the monthly periodical *Tuberculosis*, which was now in its seventh year, with a circulation of 2,800 sent to every part of the world wherever there were people interested in tuberculosis; and finally, the work of the Business Bureau of the International Association from which information was distributed on request, on every subject relating to tuberculosis. (4) A report on the work of the International Association, its discoveries and conclusions, was sent to the governments of the various countries, and thus became available material for improving legislation bearing on tuberculosis, and the methods for carrying on the campaign.

The Duties of the General Government in the Restriction of Tuberculosis.—Dr. Victor C. Vaughan of Ann Arbor read this paper. He said that governments were

formed for the security of the property and lives of its citizens. The government protected the prorperty and lives of its citizens against foreign foes. At home it protected him against the lawless of his own country. The government maintained a navy for the protection of the property and lives of its citizens against possible foreign foes, and for the suppression of riot and rebellion within its own borders. In the United States the general government regulated interstate commerce and endeavored to protect the citizens of one State from frauds that might be attempted by those living or doing business in other States. All this was proper and wise, but in this enlightened age a government should do more than this. Science had shown that disease was one of the most destructive agents to both property and life, and that many diseases were preventable; consequently the government that did not put forth every possible effort to protect the property and lives of its citizens against disease was not doing its duty. Tuberculosis was highly destructive to both property and life, and the purpose in this paper was to point out some procedures that our general government should carry out in the suppression and extinction of tuberculosis. While the researches of Villemin and others had demonstrated beyond a doubt the infectious nature of tuberculosis, and the painstaking labors of Koch had resulted in the discovery of the active infecting agent, there was much yet to be done in a scientific way before this disease could be extinguished and success in this crusade against this disease, like success in all other great undertakings, depended upon exact knowledge of details. He briefly enumerated some of the things that, in his opinion, our general government should do. The relation of human to bovine, avian, and piscine tuberculosis, also the relation of the bacillus, deserved more exact and thorough study. The possibility of modifying the bacillus by passage through more or less resistant animals should be investigated. The influence of light, of restricted or abundant air supply, of exercise, of different kinds of food on the progress of the disease in tuberculous animals were matters of importance. The question of heredity in the transmission of tuberculosis was by no means finally settled, and its importance in attempting to stamp out the disease was great. Should the tuberculous individual beget or bear children, and if he or she did so, what was the effect on the course of the disease in the parent, and what the effect on the offspring? The facts, as far as they could be ascertained, should be learned and presented to the people. The problem of immunity and of arrest of the disease should be prosecuted most exhaustively. The influence of race, age, sex, and condition of life on susceptibility to infection and on the progress of the disease is something concerning which all possible information should be acquired. The chemistry of the bacillus and the cleavage products was an important matter. These bodies should be studied both chemically and toxicologically. This alone constituted a record that might occupy many investigators for years, and it could be carried out properly only by means of extensive and costly equipment. The disinfection of houses occupied by consumptives was a practical matter of great importance and the same was true of the means by which the traveler might best protect himself from infection. All these and many other problems, which must be solved if the race were to rid itself of this disease, could best be done by investigators working in laboratories built, equipped and sustained by the general government, and the government should enter into and carry on this work for the following reasons: (1) It was for the public welfare. (2) It would demand the time and attention of men who should be relieved of the necessity of doing anything else. (3) It would require such expenditures that it could be best done under special official regulations and at governmental expense.

A Comprehensive Program for the Prevention of Tuberculosis; the Relative Functions of Available Agencies.—Mr. Livingston Farrand of New York said that tuberculosis could be eradicated only by eliminating the centers of infection and by raising the resisting powers of the individual. The former depended upon adequate facilities for early diagnosis, for treatment of curable cases, and for the proper care of advanced cases, and upon restrictive sanitary measures. Increasing the resisting powers of the population depended upon a higher standard of living and a wider observance of sound hygiene. Local official authority was of more direct assistance than national or State agencies. Private agencies, as dispensaries, sanatoria, and hospitals, were necessary in arousing public interest and in educating the public until public authorities could be made to see and assume their duties in this field. Hospitals for advanced cases were a great present need in the United States.

The Function of Relief Agencies.—Mr. Francis H. McLean presented certain statistics showing the limited work done outside of large centers and showing how difficult it was to secure so rudimentary a thing as the registration of cases. He thought it was the function of relief agencies in smaller places to organize tuberculous work rather than to have separate associations. The function of such agencies should not vary with reference to agitation for the passage and enforcement of wise legislation. The trouble had been that smaller associations had attempted their own educational campaign, and had effected comparatively little, while they had not encouraged the healthy growth of State and local health boards.

The Unteachable Consumptive. Ellen N. La Motte of Baltimore said that it must be remembered that there was a class of consumptives that could not be educated, the class which was most prone to tuberculosis, and that in preventing tuberculosis it was not the occasional but the constant use of adequate precautions that could check its spread. In her experience with 1,160 cases from this class, only 143 were fairly careful; 719 careless and 289 grossly careless. Any community where such a class was known to exist was justified in adopting more radical measures than education as a method of checking the spread of tuberculosis.

Industrial Insurance in Relation to the Contest with Tuberculosis.— Prof. Charles Richmond Henderson of Chicago showed that present methods of meeting the cost of tuberculosis in the United States were entirely inadequate. The mutual benefit societies were unable to carry their invalids more than a few weeks. In Germany every workingman had sickness and invalid insurance, to whose funds he contributed when well and to whose funds he had a legal right without charity when he was sick. Consequently he kept himself under medical care and had the best possible chance of being restored to health. While he was helpless his illness was not aggravated by anxiety for his family.

The Antituberculous Dispensary in Lyons, France.— Drs. F. Arloing and Paul Courmont of Lyons, France, described this institution, which was modeled on the Calmette type, and was devoted chiefly to hygiene and prophylaxis. Every patient was subjected to a medical examination, the sputum examined, and his home inspected. The patient was attracted by the therapeutic feaeture of the institution, where he received both treatment and assistance, while prophylaxis, which was the real object of the undertaking, was carried out by providing the patient with a spit cup and giving him instructions in hygiene and by disinfecting his dwelling house under the supervision of the inspectors. The family wash was disinfected in a laundry which was organized like that in the Calmette dispensary. The patient was given all possible facilities for cleanliness in the hydrotherapeutic establishment.

The Relation of Tuberculosis to Crime and the Incarcerated Criminal.—Dr. Julius B. Ransome of New York thought that the fact that most prisoners came from infected areas of population would signify that crime and

tuberculosis were more or less closely allied. The tuberculous prisoner represented one of the greatest physical menaces to the general social order. The necessity for a law making mandatory the examination of every prisoner admitted to every penal institution was absolute. The history of the tuberculosis work at Clinton Prison illustrated the advantageous results possible from the special treatment of the tuberculous incarcerated criminal. There had been a decrease of 71 per cent. in the death rate from tuberculosis in the prisons of New York State in the last fifteen years. The penal institutions offered an opportunity for prolonged experiment and study which could not be found in any other field.

The Study of the Relation of Prostitution to Tuberculosis.—Dr. J. Willoughby Irwin of London contributed this communication, which was mainly statistical. Out of 218 women examined, 174 used tobacco, alcohol, opium, and cocaine, singly or all together. Of the 174, 72 were tuberculous. Thirty-two gave family histories of tuberculosis; 38 gave histories of disease that greatly predisposed to tuberculosis. The subject of pregnancy and miscarriage was gone into, and the percentage among the tuberculous and non-tuberculous was about the same. Forty-six of the tuberculous prostitutes did not have any history of contagion. Their living conditions were as a rule good. What slight information in regard to venereal diseases that could be obtained seemed to indicate that this class of diseases predisposed to tuberculosis, and if acquired after the tuberculosis hastened the progress of the latter.

Some of the Difficulties (Professional and Social) of the Early Recognition of Tuberculosis and Some Suggestions as to the Remedy.—Dr. E. O. Otis of Boston said that the early recognition of tuberculosis was not only of extreme importance to the patient, but equally so to the community, for, as Professor Grancher said, if it was treated and cured at an early stage it ceased to be contagious. It had been estimated that the ascertained mortality from consumption in any city was only one-tenth of the real number already seriously affected with the disease; hence a very considerable number remained undiscovered; and a very large number of these undiscovered cases must be in the early stage of the disease.

Institutional Care for the Early or Advanced Consumptive; Which is the More Important? Experiences and Conclusions of a Layman.—Mr. Jacob H. Schiff, President of the Montefiore Home for Chronic Invalids of New York, said that, as the result of almost a quarter of a century's experience as chief executive of a large private philanthropic institution which dealt with consumption in every stage of the disease among the dependent classes of the tenement population of New York City, he had become convinced that if the scourge was to be dealt with effectually one must plan more largely than hitherto and much more boldly. His observations and thoughts on the subject had led to the formulation of a few general principles for comprehensive action: (1) That the private hospitals and sanatoria exclude from admission advanced cases and incurable consumptive patients. (2) That the State make ample and adequate provision for the proper care of sufferers from advanced and incurable consumption, and that the isolation of phthisis sufferers in an advanced stage be made compulsory by law. (3) That ample provision be made in sanatoria and otherwise for the scientific treatment of the consumptive in the early and curable stage of the disease, both through private philanthropy and by the State. (4) That a thorough system be organized through which can be disclosed the existence of cases of weakened constitutions and anemic condition in children and young persons, and that proper provision be made for curing such conditions wherever they were found to exist.

Farm Colonies and Industrial Settlements.—Mrs. James E. Newcomb, President of the Stony Wold Sanatorium, New York State, said that of the patients discharged from this institution since its opening up to the present time, 97 had died, and the question was suggested, How many of them might have been saved? Would it not have been wise to have expended a few more dollars on them at the time of discharge? Could suitable employment have been found for them under proper climatic conditions? In an endeavor to answer these questions, they decided to start an industrial settlement or farm colony; discharged patients were called upon to do light work. Members of the patient's family could find employment there. A small beginning had already been made.

A Farm Colony Experiment.—Dr. Henry Barton Jacobs of Baltimore presented this paper as a preliminary report upon an experimental farm colony, which had been established by the Hospital for Consumptives of Maryland at the Eudowood Sanatorium. In spite of the unfavorable season which prevailed, the value of the crops raised would be a little over the expense of the experiment.

What is Necessary for the Comprehensive and Adequate Treatment of the Tuberculous Problem?—Mr. Victor G. Bloede of Baltimore discussed this proposition under the following five propositions: (1) The best method of practically organizing and conducting the fight and enlisting the sympathies and securing the coöperation of the various communities, and all classes of the public, in this great work; (2) the best method for discovering, treating, and controlling cases of tuberculosis, the home care and treatment of patients, and the best method of controlling the admission to hospital and sanatorium; (3) the primary importance, in a comprehensive plan for the handling of the problem, of the care of the advanced cases; (4) the treatment of the early and incipient cases in its relation to the whole subject; and (5) the important matter of the care of that large class of patients whom the disease had left in a condition preventing them from returning to their former avocations or doing hard or continuous work of any kind.

Fourth Day—Thursday, October 1.

Elementary Instruction as to Tuberculosis.—A. E. Winship of Boston said that if the pupils in the elementary grades were so overworked that there was not time to teach the prevention of tuberculosis, it was time to eliminate some of the rubbish from the present school program. As much disciplinary value could be obtained from the proper teaching of hygiene as from other subjects that were now taught in the schools.

The Body of the Bacillus; Which Shall be Emphasized in the Hygienic Education of the Public?—Dr. Howard S. Anders of Philadelphia said that anti-tuberculosis instruction of a well balanced type should receive as much time and care as anti-alcoholic instruction in the public schools, academies and colleges. He made reference to the historic swing of emphasis from the idea of heredity and debility to the germ menace; now backward to a degree, to more rational attention to the wide importance of various predisposing and direct causes of bodily susceptibility in domestic, social, industrial and commercial conditions. There was no reason or safety in neglecting the microbic factor in relation to sanitation, but it was probably better to teach with greater emphasis the importance of preserving vital resistance, or invigorating it, by improvement of living, working and traveling conditions. Sanitary prophylaxis was therefore a valuable part of education, but the preponderance of education should be directed along lines of sustaining and increasing bodily health and vigor.

Hygienic Instruction in Schools.—Dr. Henry Barton Jacobs of Baltimore stated that in order to control tuberculosis it would be necessary to rely in the past instance upon education. Hospitals, sanatoria, dispensaries, and camps might have great influence in alleviating or curing those infected with tuberculosis, but their great influence in checking the spread of the disease was found

in their educational influence. These institutions became schools in which hygiene was taught. The inmates and their friends belonged to the adult population, and it was to the men and women of the future that we wished to give this instruction. If the same kind of instruction could be given them we would be sending out into the world youths ready for the emergencies of life and with an understanding of how to avoid preventable diseases. Until the schools made provision for this kind of instruction we could not hope to cope successfully with tuberculosis and other infectious diseases.

A Proposition to Introduce a Public Health Week into the Public Schools.—Dr. CHARLES WARDELL STILES, U. S. Public Health and Marine Hospital Service, of Washington, said that, as the result of his investigations in the South, he proposed the introduction of a "Public Health Week" into the public schools, in order to teach the following three great hygienic principles to the children: (1) Do not spit on the floor, for this habit spreads tuberculosis and diphtheria; (2) do not pollute the soil, for this habit spreads typhoid fever, and ground itch, with its resulting hookworm disease; (3) protect against mosquitos, for mosquitos spread malaria, yellow fever, dengue, and elephant foot. This proposition was met with favor, and if certain legal points could be arranged, the plan would be put into active operation this coming year. The plan involved the issuance of popular circulars by the U. S. Public Health and Marine Hospital Service, which the State superintendents of instruction could adopt as text-books, to be used in the physiology classes during public health week.

The Social Significance and Educational Value of the Nurse in Tuberculosis Work.—Miss LILLIAN D. WALD, head worker, Henry Street Settlement, New York, reviewed the work since the first organization in America of the District or Visiting Nurses' Association in 1877. Social significance lay in the ability of the "soldiers" to care for the individual victims and to throw light upon the whole subject and the multiple questions involved.

Tuberculosis and Two Thousand Dollars a Year.—Dr. HELEN C. PUTNAM of Providence, R. I., Chairman of Committee to Investigate the Teaching of Hygiene in Public Schools, appointed by the American Academy of Medicine, said that many houses occupied by intelligent people with small incomes invited tuberculosis through unsanitary sites and flimsiness of structure, yet for them high rents were demanded. The only effective way of reaching these people was through regular educational institutions. This Congress should demand practical training in hygiene and sanitation in schools and colleges by competent instructors, and equally insist upon efficient industrial training. This Congress and its affiliated associations should have central committees on school and college instruction in hygiene and sanitation.

The Popular Lecture in the Crusade Against Tuberculosis.—Dr. S. ADOLPHUS KNOPF of New York said that, while the distribution of literature to enlighten the people in the prevention of tuberculosis was most valuable and indispensable, the spoken word, the popular lecture, by a competent physician, was equally important. The place for such a lecture should be a public hall, schoolhouse or church, easily accessible, well lighted and well ventilated. The lecture should be free to all, the cards of invitation attractive and the wording dignified. The public press should be invited to the lecture, but it was best to give an abstract of the address to the reporters present so as to avoid the appearance of false or misunderstood statements in the press. A well prepared lecture without manuscript was preferable to the reading from manuscript; but a well read and carefully prepared lecture was preferable to a rambling and disconnected extemporaneous talk. A popular lecture should, as a rule, not be longer than three-quarters of an hour; fifteen minutes should be allowed the audience to ask questions.

The Blue Star: A Simple and Practical Way to Interest People in Tuberculosis and to Raise Funds to Combat the Disease.—Miss CLARA E. DYAR of Detroit, Mich., gave an account of an effort to raise funds for the prevention and relief of tuberculosis by a voluntary association entitled the Blue Star. The work of this association had proved so effective as to suggest its introduction to the International Congress for use in similar efforts.

Report on the Teaching of Elementary Hygiene in the Training Colleges and Elementary Schools of Great Britain and Ireland.—Dr. G. A. HERON, Delegate of the Royal Society of Medicine of London, said that in England and Wales a great step had been gained in the cause of school education in hygiene. On August 1, 1908, ended the evil system which, till that date, allowed the study of hygiene to be optional with those who meant to become school teachers. When the students completed their course at the training school a part of the examination was a special paper on hygiene. In Scotland all the training colleges had courses of instruction in hygiene. In England, Ireland and Wales the teaching of hygiene had, until to-day, been behind the times, but this was not so in Scotland. Sound education in hygiene, given both to school children and to adults, was the chief means by which they could not only immensely lessen, but practically end, the existence of tuberculosis.

Tuberculosis and the Public Schools.—Dr. LUTHER H. GULICK, Director of Physical Training in the Public Schools, New York, presented this communication, in which he emphasized the importance of attacking the problem through the agency of the public schools. With the development of a democracy which depended upon the intelligence of all the citizens, the State had to adopt general education as a measure of self-protection. These were the reasons why the State must, through the same agencies, protect itself from these ravages of disease which were dependent upon ignorance with reference to the fundamental facts of life. How so to manage the home organization as to live most effectively had only recently come to be regarded as one of the basal elements in general education. It was, therefore, as yet not treated as a prominent topic in the curricula of our normal schools or colleges. In practically no normal school was it yet ranked with such sciences as phychology, education, history, and the like. The State, in order to protect itself, must bear as definite a relation to the health of its children as it did to their education. These two purposes must be administered in the main by a single department of our government, namely, the public school. Hence, it was inevitable that there should be established as part and parcel of our department of education, groups of medical experts who should see not only that the school was conducted without injury to the health of the school children, but that they were a positive factor in raising up for our republic that body of citizens which were not only intelligent, but which had that background of vitality and power, without which education, science, philosophy and art were relatively valueless.

Diagnosis and Treatment of Infantile Paralysis by Electricity.—Delherm advocates the use of electricity for purposes of diagnosis, prognosis, and therapeutics early in any case of infantile paralysis. The sooner this treatment is begun the better results we may expect to obtain, while no case of this disease fails to be benefited by it. The author begins this treatment as early as the fourth week, using the galvanic current applied to the spine without any interruptions, or passed through the limb by means of a waterbath. It stimulates the circulation by vasodilatation, raises the temperature of the limbs, and limits the atrophy which will inevitably occur. Later in the case the galvanism is applied with interruptions, three times a week, to the paralyzed muscles. The use of faradism is generally not advisable, either because the muscles do not respond to it, or because tetanization favors atrophy.—*Annales de Médecine et Chirurgie Infantiles.*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City for the weeks ending October 3 and October 10, 1908:

	October 3		October 10	
	Cases	Deaths	Cases	Deaths
Tuberculosis Pulmonalis	481	153	597	156
Diphtheria	266	21	284	18
Measles	96	2	68	—
Scarlet Fever	102	4	146	4
Smallpox	—	—	—	—
Varicella	—	—	19	—

Cerebrospinal Meningitis	7	5	3	1
Malarial Fever	—	—	—	—
Totals	1073	206	1258	196

Pyometra in Cancer of the Uterus.—André Lomon says that cancer of the uterus is the cause of pyometra in most cases, and that it occurs in old women who have long passed the menopause, as a result of the occlusion of the cervical canal by senile sclerosis. With a normal mucous membrane there would be no contained fluid, but the cancer causes metritis and the increased secretion is retained in the cavity. The condition may be latent and the diagnosis be made only at operation for the removal of the tumor. Or the condition may be intermittent and relieved at times by evacuation after a severe attack of uterine colic. The prognosis of the condition as such is not bad, the only complications to be feared being rupture of the collection into the peritoneal cavity. Treatment of the condition is by catheterization of the uterus, or forcible evacuation through a passage made through the resistant cervical tissue.—*La Tribune Médicale.*

Syphilis and Tuberculosis.—Auguste Guérin says that the treatment of puerperal fever, which he has tried in is often difficult. When both exist at the same time it is still more difficult. In the presence of tuberculosis we should pay great attention to leucoplakia, aortitis, and pupillary troubles. This triad will make the diagnosis easy. Clinically syphilis may simulate tuberculosis. We may have it under the form of laryngitis, bronchitis, and pleurisy, as well as other pulmonary forms of disease with all the classic symptoms of tuberculosis. Syphilis is a predisposing cause of tuberculosis. It prepares a proper soil for the tuberculous germ. Scrofula is a derivative of family syphilis and this may be the cause of the occurrence of adenoids and appendicitis. A patient affected by tuberculosis may receive his death blow by contracting syphilis, or with a slow form of tuberculosis he may be aided in its cure by the reception of syphilis. Tertiary syphilis is generally benign with tuberculosis. This results from the formation of arteriosclerosis as a result of the syphilis. It produces cavity formation in young persons which does not result from pure tuberculosis. Mercurial treatment is useless in acute tuberculosis and in the last stages. It is bad in ulcerations of the tongue. In many cases on the other hand it may be used without fear in form of inunction, injections of soluble salts, or by mouth. Insoluble salts should not be used for injection, nor should iodide of potassium be given. A full diet should be added to the treatment.—*Journal de Médecine de Bordeaux.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending October 2, 1908:

SMALLPOX—UNITED STATES.

			Cases	Deaths
California, San Francisco	Sept.	5–12	4	1
Indiana, Indianapolis	Sept.	14–20	1	..
Lafayette	Sept.	15–21	1	..

THORACIC PERIOSTEEDEMA OF ANGIONEUROTIC ORIGIN.

By HEINRICH STERN, M.D.,

NEW YORK.

The exploration of the thorax occasionally reveals a more or less pronounced and circumscribed swelling over one or more ribs, over the sternum, or more rarely over a costal cartilage. This swelling, unlike the superficial angioneurotic edema, appears to have its source in the periosteum or the perichondrium; it does not necessarily concur with any distinctly painful sensation in the involved area, and is of a fleeting nature. The swelling consists of a firm, doughy infiltration of the tissues in the immediate proximity of the osseous or cartilaginous structures of the thorax and is prone to recur at irregular intervals.

A short time ago, Max Herz described substantially the same syndrome as pseudoperiostitis angioneurotica,* apparently assuming, however, that it is an affection sui generis. Lublinski† has since published a case-history under the same caption. Herz speaks of an "affection" consisting of the tissue-infiltration in the immediate neighborhood of a bone, causing pain, sensitive to pressure, and following in the wake of angioneurotic cardiac paroxysms.

The nosological status of the syndrome, as given by Herz, is quite vague. In the first instance, it is unfortunate that we try to identify a pathological condition by a negative designation; a pseudoperiostitis is a false periostitis, which means that it is not at all a periostitis in the common acceptation of the term. We should always attempt to identify an abnormal, and for that matter also a normal, state by its positive and prominent phenomena. The condition before us is characterized by a circumscribed, fleeting edema which is connected with the periosteum. It is therefore a periosteedema on an angioneurotic basis. The term periosteedema is certainly more expressive of the pathological state than is the appellation pseudoperiostitis. Herz believes to have described an affection which was hitherto unrecognized. This is certainly not the case, for we know that angioneurotic edema may occur in the form of periosteal swelling surrounding the ribs and sternum. Angioneurotic periosteedema, however, is by no means confined to the bony structures of the thorax as we may encounter it connected with the bones of the head, the pelvis, or the extremities.

It must not be wondered at that Herz observed his pseudoperiostitis only in the thoracic skeleton and in conjunction with a cardiac neurosis, as his experience was gained in the diagnosticotherapeutic institute for cardiopaths in Vienna. Had his work brought him in closer contact with patients who were not cardiopaths, there is little doubt that he would entertain a somewhat different opinion concerning fleeting periosteal or perichondrial swelling.

While angioneurotic periosteal edema may supervene practically everywhere where there is periosteum, its occurrence on the thoracic bones neither depends upon a cardiac neurosis nor is it a concomitant of the latter in the great majority of instances. It seems to concur much more frequently with gastrointestinal disturbances, which may themselves be of angioneurotic production.

Thoracic periosteedema of a transitory character is not as uncommon a phenomenon as one may presume. As a matter of fact we are apt to overlook a slight swelling over the ribs or the sternum unless our attention is especially drawn to it by the patient or someone of his surroundings. At other times the patient is quite unaware of the swelling, and is certain that it was not present a few hours ago. Again, in other instances the infiltration does not exist at the time of examination, but the patient is positive that there was a swelling somewhere on the chest a short time before. As already remarked, a distinct pain is not always a concomitant of the phenomenon, and when it is present, it is often quite insignificant; the pain, as a general rule, however, is more pronounced than when skin and mucous membranes alone are involved. A painless or nearly painless evanescent tumefaction on the thorax necessarily escapes detection in a goodly proportion of instances.

While thoracic periosteedema of angioneurotic causation may not be particularly painful in itself, a pressure pain may invariably be elicited at the site of the affected bone during the period of infiltration. This pressure pain, which may be quite acute at times, can often be called forth when the externally visible infiltration has subsided. In some instances, the pressure pain can be evoked weeks and months after the disappearance of the swelling, a fact which points to the existence of a chronic, circumscribed periostitis. An affection of the costal periosteum can as a rule be readily localized by means of the pressure pain, a point which is of decided value in differential diagnosis.

Thoracic periosteedema of angioneurotic origin is invariably circumscribed and appears and disappears quickly, but not as suddenly as the angioneurotic edema of the more superficial structures. It tends to recurrence at irregular intervals but at the same location. Unlike the common angioneurotic edema which generally ensues before the thirtieth year it does not, as a rule, supervene until after this period of life. In my experience it has occurred much oftener in women than in men, and it invariably ensues in persons with neurotic tendencies. Once in a while two or more instances of angioneurotic periosteedema are encountered in one family. Irregular menstruation or the cessation of the catamenia seems to favor its production. While superficial angioneurotic edema is mostly multiple, there occurs usually but one swelling in thoracic

*Zentralblatt für innere Medizin, March 21, 1908.
†*Ibidem*, May 2, 1908.

angioneurotic periosteedema. I have seen but one case with multiple infiltrations, none of which, however, was larger than about two centimeters in diameter. The thoracic periosteedema may attain considerable size, it may involve two or more ribs, a portion of the sternum, and may be continuous over the interposed costal cartilage by the agency of the latter's perichondrium. Its usual dimensions vary from that of a longitudinally halved pigeon's egg to that of one-half of a good-sized apple. The circumscribed tumor is palpable in nearly every instance, that is, the swelling generally occurs where there is the least resistance, and this is on the external surface of the thorax. In other cases the edema may extend into the thoracic cavity, or may even be confined to it, and may give rise to "asthmatic" attacks, dyspnea, cough, cardiac irregularities, and a variety of disturbances of the intrathoracic equilibrium.

The temperature of the infiltrated area is usually somewhat raised, but hardly ever more than about two degrees Fahrenheit. In some instances, the surface temperature appears to be somewhat diminished. The fluctuations of the local temperature are of brief duration, being most pronounced during the productive stage of the infiltration. The local temperature alteration does not correspond to the extent of the area involved and does not reflect the degree of the swelling. Thoracic periosteedema, being a localized process, does not as a rule influence the general body temperature. If fever occurs at all it is of a very mild degree unless it be the expression of an accompanying affection.

The predilection of the swelling to appear and reappear as a periosteal edema, besides being due to an angioneurotic factor, must be founded in some structural abnormality of the bone. This may be the consequence of malnutrition, a rachitic condition, for instance, or it may be the immediate or mediate result of an injury. S. West has reported the histories of acute periosteal swellings in several young infants, which swellings, he opines, were probably rickety in nature.* While I have never seen in infants and children any periosteal swellings apart from those due to subperiosteal hemorrhages occurring not infrequently in infantile scurvy, and, of course, the cephalohematoma in the new-born, my cases having been almost invariably of the acute superficial variety, I could deduce early rachitis in at least fifty per cent. of the instances of thoracic periosteedema which have come under my observation. In some of my cases in which traumatism proved the direct cause of the fleeting periosteedema a clear history of rachitis could be obtained. Other instances of the phenomenon which I have seen were due either to an injury or to refrigeratory influences. A slight hurt of the thorax may give occasion to an evanescent periosteedema in individuals prone to angioneurotic disturbances. These are the cases which pass off unnoticed, as a rule, because neither patient nor physician pays sufficient attention to them. The phenomenon ensues more frequently in the cold season, and the greater frequency of it among women, I think, is due to their scanty attire of the chest, more especially at social functions, etc. Many an uneasiness and pain in the female chest arising the day after the dance are probably due to the periosteum and its infiltration and have nothing to do with "neuralgia," "pleurodynia," "muscular rheumatism," "pleuritis," etc. Were we to examine carefully all these cases we would certainly find slight localized edemas and pressure pains over a rib, a costal cartilage, or a portion of the sternum, in a large proportion of instances.

Thoracic periosteedema does not require much treatment, as a rule; its recognition, however, is not unimportant because it averts all kind of useless medication directed to affections which are not present, or which are but secondary to the periosteal anomaly. Periosteal disease is one of the principal mechanical factors of "neuralgia," for instance, therefore we should not treat the vague symptom "neuralgia," which is to no real purpose, but its underlying cause. Hot applications to the diseased spot, and when we have an active inflammatory process the continuous employment of the ice-bag will relieve the "neuralgia" much more readily than opiates, salicylates, or the coal-tar derivatives. Counterirritants have no place in the treatment of periosteedema, and massage, electricity, and vibration, are worse than useless. Bier's hyperemic treatment may be given a trial if the edematous swellings appear too frequently and cause discomfort. In two cases of oft-repeated and painful periosteedema I obtained excellent results, so far as diminution of the frequent recurrences and suppression of the pain were concerned, by means of continued dry cupping. If the pressure pain persists after the swelling has subsided it is best to treat the affected area like a fractured rib by strapping it with strips of zinc oxide adhesive plaster which should be applied from below upward and at the end of expiration.

Constitutional treatment should be instituted only when the patient is a confirmed neurotic. Mental rest is then always indicated. Hydrotherapeutic procedures may afford relief of the contributing neurotic condition. A sojourn in some other altitude may also tend to the amelioration of the systemic state and the localized angioneurotic phenomenon. Constitutional treatment may be called for when the subperiosteal infiltrations cause intrathoracic pressure-symptoms evidencing themselves by respiratory and cardiac disturbances. Powerful suction cups will be here of decided assistance, and the Bier hyperemic method (Stauungshyperemie), which I have had as yet no occasion to employ in such instances, ought to render excellent service. The latter, however, is a suggestion which I advance on purely theoretical grounds.

In the following I shall briefly mention some instances of thoracic periosteedema which have come under my observation.

Case I.—Mrs. M. B., 34 years old, mother of two children. Was referred to me on account of bradycardia and attacks of dyspnea. Seizures occurred about weekly, started at night, and lasted for almost two days. There was a feeling of oppression and some pain extending from the second to the fourth rib, and from the left sternal to the left mammillary line during the time of the attack. Patient exhibited neurotic stigmata and had been treated for "rheumatism" on account of fleeting swellings in the knees, calves, legs, hands, and face. The swellings were more pronounced at the time of menstruation, and not all the parts were edematous at one and the same time, as a rule. The physical examination revealed besides a slightly arhythmic heart, a circumscribed, dense, non-pitting infiltration extending from the second to the fourth left rib, having its maximum elevation in the left parasternal line at the inferior border of the third rib. There was a distinct pressure sensitiveness. Continued deep palpation and rather slight pressure upon the tumefaction called forth very shallow, jerky respiratory movements, increased dyspnea, and

British Medical Journal, 1888, Vol. I., p. 856.

arhythmia, and a good deal of anxiety. The general temperature was not augmented, but the surface of the infiltrated area felt decidedly warmer to the touch than the surrounding normal integument. At the time of a second examination, five days later, the tumefaction had entirely disappeared, but there still remained some painful periosteal spots upon pressure; the patient felt decidedly more at ease and did not any longer complain of intrathoracic oppression. In another five days the phenomenon, and with it the dyspnea and augmented arhythmia, had recurred.

This case shows that acute superficial edema and acute periosteedema may occur in one and the same person, and that there may have existed an evanescent, frequently recurring periosteal swelling, together with the external infiltration, on the inner side of the thorax which may have been the disturbing factor of the intrathoracic equilibrium. It is possible, however, that the visible periosteedema always occurred synchronously with a superficial fleeting edema of the bronchial mucosa, and that the dyspneic seizures, and presumably also the arhythmic behavior of the heart, were the result of pressure emanating from the left bronchus or its ramifications.

Case II.—Mrs. F. S., 36 years old, mother of five children. Was referred to me on account of diabetes mellitus and "rheumatism." She experienced swellings in the joints, the arms, legs, the face and chest, which would come and go. The first swelling occurred eleven years ago, shortly after childbirth. There never occurred any fever with the swellings, and the accompanying pains were not acute and were likened by the patient to "stiffened pressure." The patient was highly neurotic and exhibited a small amount of glucose in her urine. The sugar never amounted to more than 25 grams in the 24 hours. She had no polyuria, and it appears that she never had had any. She complained of no respiratory or cardiac difficulty. The examination of the chest showed a distinct, circumscribed infiltration over the sternum, which was not painful in itself but which was very sensitive on moderate pressure. The pressure pain extended somewhat to the right, traveling along the fifth rib. The patient stated that about half the time there was a swelling over the breastbone, and that she preferred to wear no corsets during that period.

This case confirms the observation made in Case I, that superficial angioneurotic edema may occur with thoracic periosteedema in the same person. This patient, a confirmed neurotic, was singularly free from respiratory or cardiac disturbances.

Case III.—H. G. H., 59 years old, banker, father of two children. Very good family and personal history. The patient had no neurotic tendencies but was subject to catarrhal conditions of the upper respiratory tract. He had had influenzal infections in two consecutive winters. The patient had been affected with some periosteal swellings in various locations at different times. On one occasion he had a very painful periostitis with extensive infiltration in one finger; on another occasion he had a periosteal inflammation of the posterior portions of the left fourth and fifth ribs extending to beneath the left scapula; on a third occasion the periosteum of the left third rib was infiltrated and caused a good deal of pain. The swellings in these instances disappeared together with the underlying cause, and have never recurred. However, the patient had from time to time another swelling which, apparently, had its seat in the periosteum, was circumscribed, painless, and not very sensitive to pressure. It was located over the left fifth, sixth, and seventh ribs, and extended from the left sternal line to about two centimeters beyond the left mammillary line, imparting to the entire area a quite prominent additional convexity. The swelling was evanescent but of longer duration than the other periosteedemas on an angioneurotic basis which I have encountered. The maximum infiltration generally lasted a few weeks, and might not reappear for a number of months, but the swelling never vanished completely.

This case is interesting for two reasons, first, because it evinces that we may find periosteedemas which are rather of a subacute than an acute nature; and, second, that there may be a tendency to periosteal disease in individuals developing periosteedema through angioneurotic influences.

Case IV.—Mrs. S. P., 34 years old, no children, was referred to me on account of "stomach disease." Ten years ago the patient underwent an operation for pyosalpinx. She complained now of pain around the heart, a bloated feeling in the same region and in the upper part of the stomach, and anorexia alternating with a voracious appetite. Pain and bloatedness would prevail for about four or five days at a time; she would feel pretty well for about the same length of time when the former symptoms would again supervene. Anorexia was present during the period of oppression, the appetite became ravenous the moment she felt better. A very thorough examination did not reveal any abnormal condition of the lungs, pleura, heart, or stomach; a test of the stomach contents showed no functional disturbance of the gastric organ. There was, however, a well circumscribed protrusion in the region of the left fourth, fifth, and sixth ribs which extended from the mammillary line to the left middle axillary line. This protrusion proved to be due to a very firm infiltration which was quite smooth over its surface, and which seemed to be derived from the periosteum of the three ribs. The dense consistency of the swelling prevented palpation of the fourth and fifth intercostal spaces. The edema itself did not cause any special pain in the protruding integument and its neighboring tissues; pressure upon it, however, elicited acute pains all over the involved area. The patient was under my observation for some time and I had occasion to watch the fluctuations of the periosteedema. Soon after the institution of treatment (application of heat, strapping, etc.) the swelling subsided and with it the subjective phenomena. For a period of nearly three months the patient felt more comfortable than she did at any time during the past ten years, and the swelling had not returned. The swelling recurs now from time to time; it is, however, much less pronounced than formerly and does not coincide with much pain, nor are the gastric symptoms present in the former degree.

The only remarkable feature of this case is the fact that the patient was under treatment for "stomach disease" for a period of ten years, and that during all this time no thorough examination of the cardiac and epigastric regions was made.

Case V.—Mrs. S. C., 36 years old, no children. The patient experienced latterly, shortly after menstruation, pain in the right ovary, precordial pain and a sense of weight in the chest, and attacks of cough, especially during the night. These phenomena gradually subsided as the menstrual period approached, but revived when this had passed. The ovarian pain was probably due to a post-menstrual congestive state which might bear some relation to a deep-seated angioneurotic edema. The chest was well developed, and there were no structural changes either in the lungs or in the heart. The uvula was

slightly edematous and the larynx appeared congested. There was a firm circumscribed elevation over the fourth rib just on the parasternal line. The swelling was about three centimeters in diameter and painful when pressed upon. It did not pit and appeared to spring from the periosteum. Observation demonstrated that the swelling was of a semi-fleeting character, that is to say, it never became entirely reduced, but that it diminished to a greater or lesser degree at about the second or third week after menstruation.

The little periosteedema, a negligible factor by itself, attains some importance as a diagnostic symptom. It throws light upon the intrathoracic condition after the catamenia because it points to the production of fleeting edemas in certain parts of the mucosa of the respiratory tract at that period. To these intrathoracic angioneurotic edemas may be ascribed the precordial pain, the sense of weight in the chest, and the coughing seizures.

Conclusions.—Thoracic periosteedema of angioneurotic origin occurs much more frequently than is generally supposed; it is closely related to the acute circumscribed superficial edema, with which it may be associated. It may be the external manifestation of periosteal swellings on the inner side of the thorax, or it may be the visible evidence of possible angioneurotic edemas of the mucosa of the respiratory tract disturbing the intrathoracic equilibrium. If rightly interpreted, it will always prove of diagnostic aid. The phenomenon, which is of a fleeting nature but tends to recurrence, appears oftener in women than in men, and seems to stand in some connection with the catamenia. A prognosis as to the period of its ultimate disappearance cannot be made, but the outlook concerning its gradual diminution and that of its concomitants is very encouraging. The phenomenon requires no treatment in the majority of instances; remedial measures, however, when indicated, invariably call forth temporary and, occasionally, also more lasting amelioration of the subjective and objective symptoms.

SOME FEATURES OF THE PRESENT CRUSADE AGAINST TUBERCULOSIS IN NEW YORK CITY.*

By N. GILBERT SEYMOUR, A.B., M.D.,

NEW YORK.

CLINICAL ASSISTANT GOUVERNEUR TUBERCULOSIS CLINIC; ASSISTANT ATTENDING PHYSICIAN CORNELL DISPENSARY (DEPARTMENT OF DERMATOLOGY).

THE importance of pulmonary tuberculosis as an economic and municipal problem has long been recognized, but its magnitude in the larger cities, and especially in New York, can best be emphasized by reference to a few recent statistics. We all know, in general terms, that tuberculosis claims annually more victims than any other one disease known to science, but that fact becomes at once more significant and more dramatic when it is expressed in numbers. Over one million deaths occur annually, in the civilized world, from tuberculosis; that is, about one in every seven deaths from any cause. Differently expressed, this means that somewhere in the world one human being dies of consumption every two minutes. In the United States, the number of deaths from consumption during the year 1907 was 150,000. In New York State about 14,000 deaths from tuberculosis are reported each year, one-tenth to one-eleventh of all deaths from every cause. In New York City, the annual number of deaths from consumption alone, exclusive of other, non-pulmonary, forms of tuberculosis, is 9,000; and in 1907, 19,725 new cases of consumption were reported to the Board of Health. Under existing conditions, the great majority of these new cases will eventually die of the disease, after infecting other thousands of their fellow-citizens.

Viewed from this standpoint alone, the outlook would seem well-nigh hopeless; but, happily, there is another aspect of the situation. Since the isolation of the tubercle bacillus by Koch in 1882, the scientific conception of the etiology and control of infectious diseases has been practically revolutionized, and the modern idea of dealing with these communicable diseases has been nowhere better expressed than by Pasteur in the sentence, "*C'est dans le pouvoir humain de faire disparaître du monde tous les maladies parasitaires.*" It is in the sanguine application of this principle that we are seeking, in New York City, to deal with the tremendous problem of tuberculosis, as it there presents itself.

In a recent article in the *New York State Medical Journal*, Dr. B. H. Waters, of the New York Health Department, calls attention to the fact that, in New York City, tuberculosis is essentially a disease of the tenements, of the crowded districts. It is there that the disease thrives and is propagated; and it is there, incidentally, that it is hardest to control. Among the wealthy or the well-to-do, patients can either be perfectly controlled in their own homes or sent promptly to one of the many sanatoria especially equipped for their care and cure. But among the poor, it is seldom possible to send away any considerable number. The majority must be treated in their own homes, in an environment peculiarly unsuited, in most instances, for the treatment essential either to the recovery of the individual, or to the protection of his family.

Our problem, then, in the control of this communicable and curable disease—for to deal with it effectively, we must recognize both its danger and its susceptibility to treatment— lies in our management of its source in the tenements; that is, in the care of the tuberculous poor.

Up to 1893, no systematic effort was made by the city to combat the spread of consumption. The high death rate and steadily increasing number of cases are accepted as a terrible, but inevitable, fact. In 1893, the first step was taken, in a law for the compulsory registration of all hospital and dispensary cases to the Board of Health; and one year later, in 1894, a further regulation was made compelling the registration of all cases of pulmonary tuberculosis. This measure met, at first, with considerable opposition, both from the laity, as represented by the press, and from the profession. It was asserted that the registration of cases would necessarily result in a certain measure of publicity for the patient, and a corresponding measure of ostracism by his neighbors. In practice, this was not found to be the case, and the regulation now meets with general acceptance and approval. It is, in fact, the essential first step in any successful attempt to combat the spread of the disease, since without a knowledge of the exact number and location of new cases no systematic effort to prevent the spread of the infection can be made. The next step of importance was taken the following year, 1895, when a special laboratory was established by the Board of Health for the free examination of sputum and for other diagnostic examinations not possible by the busy practitioner. By this means, the registration of cases is often obtained when a formal report might

*Read before the Jefferson County Medical Society, July 9, 1908.

be neglected, a positive sputum serving as its own report of a new case.

No further municipal move of importance was made, however, until May, 1894, when the first separate class for the treatment of pulmonary tuberculosis was established at the Dispensary of the New York Throat and Nose Hospital, under the direction of Dr. Bermingham. The idea of a special dispensary, or separate class, for the care of consumptives, was no novelty abroad, but it was a distinct innovation in New York City. Previous to that time, tuberculosis cases had been accepted in the general medical clinic of whatever dispensary they might happen to apply. There they had awaited their turn in the general waiting-room, without any precautions for the protection of other patients. Upon admission to the clinic, they had received such examination as could be given by the busy, overworked physicians in attendance; were diagnosed as consumptive—if they were sufficiently advanced cases to render diagnosis relatively easy—and were dismissed with a few hasty instructions in hygiene, and probably with one or more prescriptions—especially for cod-liver oil and the Stoke's expectorant mixture. This may appear to be a criticism of the physicians in question; but such an examination and method of treatment were all that was possible under the circumstances, and their futility was recognized and deplored by the physicians themselves more than by any possible critic.

With the formation of separate classes for the care of tuberculous cases, a new era was established. In a special class, it became possible, not only to make more careful and thorough examination of applicants, and thereby to recognize earlier and more hopeful cases, but also to devote to each patient the time necessary to teach him those rules of personal hygiene so important for his own improvement, and for the safety of his family and neighbors.

The first separate clinic was soon followed by others. Private institutions and city dispensaries adopted the new scheme with enthusiasm, recognizing its need and its value. Among the city hospitals, Gouverneur was the first to establish a separate Tuberculosis Clinic in October, 1903, followed by Bellevue Hospital in December of the same year. Harlem Hospital was added to the list in 1904. Meanwhile, Vanderbilt Clinic opened its class in January, 1903. The model Board of Health Clinic, planned and built under the direction of Dr. Hermann M. Biggs, with the assistance of Drs. Knopf, Billings, and Waters of the Health Department, was opened on March 1, 1904. More recently, New York Dispensary and New York Hospital, Presbyterian, Mt. Sinai, and the German Hospital, have joined the ranks, and there are now branches of the Board of Health Dispensary in Brooklyn and the Bronx.

The first evident effect of these separate clinics was the more thorough examination and the more efficient treatment of the cases themselves; but it became evident very shortly that the most essential feature of a really effective control of such patients, that is, their obedience to sanitary and hygienic regulations in their own homes, could only be taught and enforced by home supervision. Out of the recognition of this necessity arose the demand for the most valuable single adjunct we have in the clinics—the visiting nurse. However thorough and painstaking the physicians may be in their care of the cases, it is practically impossible for them to know if their instructions are heeded or their rules obeyed, without the report of the nurse. She visits the patients in their homes, advises them how to readjust the surroundings to meet their needs and our rules, reinforces the instructions given at the clinic, and, finally, reports regularly to the doctors the home conditions she has found. It thus becomes possible to know the exact environment which has to be dealt with in each individual case, and to take systematic measures to correct or improve it.

To appreciate why this question of environment assumes an importance in the treatment of tuberculosis greater than in that of any other disease, one has only to remember that it is in the home—and especially in the tenement home—that tuberculosis is acquired and transmitted, and from every neglected case of the disease one or more new cases will inevitably arise. Here, at its very source, is where the fight must be fought—and won. If we can once control the spread of tuberculosis in the tenements, we shall be able to stamp out the disease through the city.

Next to the adoption of separate classes, the most important step in the crusade has been the districting of the city. This scheme was an outgrowth, or by-product, of the work of a committee, organized in the spring of 1906 under the auspices of the Charity Organization Society, for the distribution of a fund contributed to the Society for relief of deserving cases among the tuberculous poor. The committee was composed of representatives from the Charity Organization Society and of physicians representing each of the various tuberculosis clinics then established. In the course of their work of investigation and relief, recently reported in full, this committee hit upon a device to simplify and harmonize the routine work of the various clinics, and to avoid delay and error in locating cases. This scheme consisted in dividing the city into districts with definite and arbitrary boundaries, each presided over by one of the special tuberculosis clinics. All tuberculous cases applying for treatment in any dispensary are referred to the special dispensary for the district in which they reside. By this method, the cases under regular observation and treatment at each tuberculosis clinic are limited to the residents of that district, and the work of the clinic and of the visiting nurse is thereby simplified and brought within practicable bounds. There are now eleven such districts in the city (that is, in Manhattan and the Bronx), controlled by eleven corresponding district clinics.

Another advantage of the district plan is that it has led to greater uniformity in methods employed by the different clinics in the care of their cases, and put a stop to patients seeking aid from several different sources, thus causing confusion and duplication of work. A uniform system of transferring cases, by special cards supplied to all the clinics, and a more systematic and satisfactory record of cases at the Board of Health, were further results of the scheme. The most recent result has been in a valuable addition to the organized forces enlisted in the work by the formation of a Women's Auxiliary for each clinic. The auxiliaries are composed of women who are connected with the social, religious or charitable organizations of the district, or who are willing to give time or funds to the work, and the auxiliaries represent what has been called "social service," that is, the effort to provide for individual cases such additional care, financial or otherwise, as they may need, beyond the advice, medicine or extra nourishment we are able to provide at the dispensary.

A final outcome of the admirable work of the Relief Committee is its recent organization, at the

completion of the work for which it was originally enlisted, into a permanent association—the Association of Tuberculosis Clinics of New York City. "This Association," to quote from the recent report of its President, Dr. James Miller, "is composed of active members, who are the representatives of the various clinics, and of associate members, who are selected as representing the different charitable, religious, and social societies and institutions in the city which are coming in contact with tuberculosis as a constant social problem." The purpose of the organization, to quote again from the report, "is to enlist the active coöperation of all these agencies in such a way that in each district of the city the tuberculosis clinic may become the center to which all workers among the poor will naturally turn for expert advice upon all questions and problems which may arise in regard to tuberculosis." By means of this central organization, the work of the separate clinics can be carried on in uniform and systematic coöperation, every district having representation on the Central Committee, and all deferring to its decisions in matters of common interest.

There are two comparatively recent factors among our available forces, to which I wish to call particular attention. I refer to the Day Camp and to the Church Classes.

The Day Camp is intended to supply a place where dispensary patients may get proper out-of-door treatment under medical supervision, during the summer months, when roofs and fire escapes are not available because of the heat, parks and recreation piers are crowded to their capacity, and the interior of the tenements is intolerable. The experiment was inaugurated in New York last year, by the Relief Committee of the Charity Organization Society, when an old ferryboat, the *Southfield*, condemned for active service, was secured from the city authorities, fitted up through private contributions with all that was essential for the purpose, and moored to a pier at the foot of west Sixteenth Street. A nurse was detailed for regular duty on the boat, and physicians from the various clinics volunteered for service. Patients were sent to the boat from all the clinics, each being given a card properly endorsed by the dispensary physician, and they were required to attend with regularity. The boat was open daily from 9 A.M. to 5 P.M., a noon meal being served on board, and extra nourishment also provided twice a day. The patients were weighed weekly by the nurse, daily morning and afternoon temperatures were taken and recorded, and sanatorium discipline was taught and maintained. A limited number of cots were provided for emergencies; but advanced cases, requiring much care, were not admitted to the boat. Steamer-chairs and hammocks were provided in abundance, and books and magazines for patients able to appreciate them.

This Day Camp proved so successful that the *Southfield* has been pressed into service again this year, and is moored now at a wharf in front of Bellevue Hospital, under the immediate supervision of the Bellevue Clinic; while a second old ferryboat has recently been secured for the Gouverneur Clinic through the efforts of the Gouverneur Auxiliary, and will be open for the reception of cases within a few days.*

The other new factor to which I alluded is the Church Class. This innovation in the treatment of tuberculosis among the poor is the outcome of the work of Dr. J. H. Pratt, who started the first such class in July, 1905, under the auspices of Emanuel Church, in Boston. In January, 1906, an associate of Dr. Pratt's, Dr. John B. Hawes, started the Suburban Tuberculosis Classes, of which there are now three or four, for the care of patients living at a greater distance from the city. Later in 1906, the first Church Class in New York was organized by Dr. W. L. Niles under the auspices of Christ Church. In the fall of 1907, two more Church Classes were added to the list, one at Montclair, N. J., under the direction of Dr. Stella S. Bradford, and the second New York Class, St. George's, of which Dr. Howard and I are in charge.

The work of these church classes should, in no way, be confused with that of the dispensary clinics, and a church class is to be regarded as among the additional resources of the district in which it is situated, rather than as a competitor, in any sense, of the district clinic. The church class approaches the problem from a totally different standpoint. The district clinic must receive all cases which are referred to it and do what it can for each. It can cure a few, arrest the progress of the disease—that is, prolong the life—of more, and care for many. It is the center of the educational crusade in the district, and the proper head of the district work. The church class, on the other hand, receives a very limited number of suitable, early cases, and, by means of the resources of the organization which supports it, that is, of the church under whose auspices it works, it aims to supply its selected cases with all they need for proper treatment in their own homes. In other words, the church class receives few patients for its special care, but it aims to *cure* those few, and to cure them at home.

It is evident how the church class fits into the district scheme. It is one additional agency in any district to be utilized in the fight, and an increase in the number of such classes is an unqualified benefit to the districts with which they cooperate.

Such being an outline of the crusade in general, it may be of interest to describe the actual work in one of the districts. The routine is practically the same in all, but I am qualified to speak from personal experience only of the work in the Gouverneur Clinic with which I have been associated for nearly five years.

The Gouverneur Tuberculosis Clinic was organized in October, 1903. We started as a subdivision of the general medical clinic and derived all our cases originally from that source. We began with an average of two cases a day. We have now an average of 20 cases a day, and keep about 125 cases under constant observation. From October, 1903, to July 1, 1908, we have had 1,246 applicants for admission to the clinic. Not all of these patients were tuberculous, and, indeed, so many cases with cough were referred to us for that symptom alone, that we have had to make the rule that no new case will be accepted unless sent by another district dispensary or after examination in the general medical clinic.

Among other diseases sent us as tuberculous, the most usual are chronic bronchitis and emphysema: acute bronchitis; nose and throat diseases with cough; chronic (sometimes acute) endocarditis; and a few scattering cases of pneumonia (masked or unresolved), typhoid fever with marked bronchitis, and other conditions having cough or temperature as symptoms.

*The Gouverneur Day Camp, the Ferryboat *Westfield*, moored at Pier 53, East River, was opened for patients on July 15.

Our routine is as simple as we can make it, under the conditions in which we work. The clinic is open three days a week, Monday, Wednesday, and Friday, from 2 to 4 P.M. There are three physicians in attendance and one visiting nurse. The patients are received into the general waiting room of the dispensary, but are assigned to special benches adjacent to the rooms reserved for our use. Each patient, on presenting himself at the dispensary, is provided with a numbered card and a piece of clean gauze. The card entitles him to admission in his turn. The gauze he must hold before his mouth if he should cough or sneeze while in the building. Cuspidors are provided in plenty, in case it should be necessary for any patient to expectorate; but unnecessary coughing is discouraged and, to a large extent, controlled. Patients with paroxysms of apparently uncontrollable coughing are often benefited by the request to leave the waiting room and sit in the open air, thereby losing their turn, until they can stop coughing. No patient is allowed to cough or sneeze without putting his gauze before his face, and our older patients are so well trained that it is no unusual sight to see one of them admonishing a newcomer who had neglected the rule.

This response to training is the more encouraging when one realizes the class of patients with which we are dealing in the Gouverneur district. The overwhelming majority of our cases are foreigners, chiefly Russian and Polish Jews—Polacks and Yids in the vernacular—with a few Italians, Germans, and Irish. Occasionally Armenians and Greeks are numbered among our patients, and we have, of course, a few of English and American birth or parentage. Most of these people—the adults, at least—are very ignorant, often unable to read or write in their own language, and very few of them speak English. Their degree of intelligence corresponds to their education, and this is a factor of great difficulty in teaching them even the rudiments of hygiene and prophylaxis. Only by patience and persistence can the rules necessary for their treatment be inculcated; but we are here assisted by their devotion to their families, and by their rather touching loyalty to us. Once convinced that our orders are intended for their own good and for the protection of their children, their blind and unreasoning observance of them is wonderful to contemplate.

Upon admission to the clinic, each patient is weighed, and has his temperature and pulse taken by the clinic nurse. This is entered upon his record, and the charts are piled in order awaiting the attention of the physicians. To each patient we endeavor to give as much individual attention as our time and the number of cases permit, realizing that the successful treatment of tuberculosis depends in so large a measure upon the detailed management of each case, rather than upon any routine method of medication or care. We grow to be very well acquainted with our older patients, those who have been with us many months, and the weekly conference bears more often the aspect of friendly advice and encouragement than of a merely professional consultation.

New cases naturally receive an even larger share of individual attention. A very complete history is taken and recorded upon a chart, uniform with that used in all the city clinics, and, after having his weight, temperature and pulse, and chest measurements recorded, the patient is subjected to a thorough physical examination, the results of which are written upon his chart both explicitly and graphically, symbols and abbreviations being used after the method suggested by Dr. Knopf and introduced by him at the Board of Health clinic. Many of the applicants present lesions sufficiently marked to offer no great difficulty in diagnosis—as you will remember that our cases are now sent us only from other district dispensaries or after examination in the medical clinic, and it is the rule among the tuberculosis clinics that doubtful cases must be kept under observation for one month before being sent elsewhere. Nevertheless, we inevitably receive a certain number of very early or merely suspicious cases, and, in spite of our rule to the contrary, we also accept a few cases for examination and diagnosis sent us by the Charity Organization Society, United Hebrew Charities, and the Nurses' Settlement, organizations to which we are constantly indebted for assistance in the extra-medical care of our people.

These very early cases present the most difficult problem, from a medical point of view, that we have to meet. They come with a suspicious family or personal history, some very suggestive symptom—as cough, slight elevation of temperature, loss of weight—few or no signs in the chest, and, of course, negative sputum. These are the very cases which, if tuberculous, and recognized promptly, afford the best prognosis, and yet these are the cases most difficult to recognize. Much has been written recently on the subject of the early recognition of pulmonary tuberculosis, and there is absolute unanimity of opinion as to its great importance both to the individual and to the community; but wide individual differences of opinion are expressed as to the best way to arrive at a positive diagnosis in these suspected cases. One authority is guided largely by the family history of the patient and the history of direct exposure; another, by previous personal history and apparent predisposition. All admit the importance of thorough and repeated physical examinations; but one depends chiefly upon information elicited by percussion, another upon auscultation either direct or with the stethoscope, another upon the *x*-ray, and so on. The most conservative clinicians probably depend upon the combined evidence derived from all these sources of information.

Speaking from my own more limited personal experience, I confess that I am obliged to depend upon all available data, both of history and of physical signs, and am governed finally by the weight of evidence. In other words, I do not dare depend upon my examination of the chest alone for a positive diagnosis in these very early cases. Of physical signs, as such, if I were asked to state those which seem to me the most reliable for early diagnosis, I should say a narrowing of the area of resonance at one apex in combination with a diminished expansion on that side of the chest. Râles in certain locations are pathognomonic, to be sure; but when râles can be made out, the process can hardly be called incipient.

In any given case, a complete family and personal history, a careful search for a history of direct exposure, a period of close observation of the patient—with daily temperature record, when possible, and weekly record of weight—repeated examination of the sputum, and, finally, painstaking and repeated examinations of the chest, making use of all the accredited methods, will provide the desired data, either positive or negative, in the majority of instances. But occasionally, even these means prove inadequate, and under such circumstances we can employ one, or all, of the three standard tuberculin tests.

The ophthalmic, or conjunctival, tuberculin test was proposed by Wolff-Eisner and Calmette, working independently, in the spring of 1907, and the cutaneous, or vaccination, test, by von Pirquet, at about the same time. Since the original reports, both tests have been tried extensively in this country and abroad, at laboratories and sanatoria; but they have been used systematically in the tuberculosis clinics in New York only within the last six or seven months. We have been making routine examinations with these tests at Gouverneur since December, 1907, and will soon have the data in about 100 cases.

It is too early to make dogmatic assertions about the precise value of these tests, but the consensus of present opinion and data seems to signify that the ophthalmic reaction is a very reliable indication of an active tuberculous focus—not necessarily in the lungs, of course—while the cutaneous reaction, which is more reliable in children than in adults, suggests a latent, encapsulated, or arrested process. Neither test can be depended upon in advanced pulmonary cases, but in these cases no diagnostic test is necessary.

The technique of these tests is most simple. We use for the ophthalmic test a 1 per cent. solution of the alcoholic precipitate, and for the cutaneous test a 25 per cent. aqueous dilution of Koch's old tuberculin, both sterilized. Both these preparations are made at the laboratories of the New York Board of Health under the supervision of Dr. W. H. Park, and are supplied to us through his courtesy. In making the Calmette test, a drop of the solution is instilled into one eye of the patient, a sterilized pipette being used. The reaction should appear within 24 hours and persists about the same length of time. It consists, in mild reactions, of an injection of the caruncle of the inoculated eye, and in more severe reactions of a more or less severe conjunctivitis. I have personally never seen a serious form of conjunctival reaction from this test, but one such case occurred last winter in the wards of Gouverneur Hospital. The patient, however, gave a history of previous attacks of conjunctivitis, and may, therefore, have been locally predisposed. When one test is negative, and the case is otherwise suspicious, we occasionally repeat the test, always using the other eye for the second instillation, as we have observed that a repetition of the test in the same eye almost invariably gives a reaction, even with nontuberculous cases.

The cutaneous test is made on the anterior aspect of the forearm. After a sufficient surface has been thoroughly cleansed, a small area is scarified with a sterile needle, exactly as for an ordinary vaccination. Two inches below this area, one drop of the test solution is placed on the skin, or upon a bit of sterile cotton laid on the skin, and a second scarification is made through the solution. These two areas are then dressed separately, with sterile gauze and adhesive straps, to prevent the tuberculin vaccination from contaminating the control—and a bandage is applied over both. This reaction does not become positive before the second to the fourth day, and persists a week or more. It consists in a small, red, inflammatory area at the site of vaccination, surrounded by a white edematous areola. It varies from a reaction barely discernible, by touch or inspection, from the control, to a reaction which can be seen across the room.

We have had no experience at Gouverneur with the tuberculin injections for the reason that they require more control of the patients, and more intelligent coöperation on their part, than we can secure there. A temperature observation every four hours for several days before the first injection, and one every two hours afterwards, preferably taken by rectum, are essential to reliable data from the injection. So far as the work is being done elsewhere in New York, the results would seem to indicate that under proper control and observation the test is without danger to the patient and exceedingly delicate and reliable for purposes of diagnosis. As a therapeutic measure, it is, under our present technique, of but little acknowledged value for pulmonary tuberculosis, but is giving good results, in expert hands, in the treatment of tuberculosis of the genitourinary tract and of bones.

Once the diagnosis is established, if the patient is eligible for our clinic—that is, a resident in the Gouverneur district—he is placed upon the list of those cases under regular observation, of which, as I have said, we have about 125 on an average. When it is understood that our district is the most densely populated of any area of equal size in the world, that it includes the famous "lung block," said to produce more cases of consumption than any city block in the United States, and that there are on the records of the Board of Health over 1,000 cases of tuberculosis in residents of the district, few of whom are in the care of private physicians or under any medical supervision whatever, the character of our portion of the city crusade becomes more evident. If—or, rather, when—we succeed in bringing into the Gouverneur clinic all those known cases not under other medical care, as well as the unreported and unsuspected cases which should be detected by a systematic examination of the families of positive cases—adults as well as children—the city will have to provide us with larger quarters and more assistants, since we are already working up to our limit of time and space. Indeed, the consistent growth of the work in any section of the city will necessitate the establishment of more special dispensaries or clinics and the further subdivision of the present districts, all of which are now too large, either in area or in population, to be adequately supervised by one dispensary.

I have spoken of the importance of examination of the families of our patients, but up to the present time we have been able to undertake this precaution with the children only. A routine examination of the sputum of infants at the Babies' Hospital within the past two years has developed an astonishing number of unsuspected cases of tuberculosis, and this, together with the effort to prevent the spread of the infection among the families of our patients, has led to the routine examination of all children of tuberculous patients, the records being filed upon uniform cards supplied to all the clinics. At Gouverneur, the fashion of large families has made this feature of the work a laborious one, one hundred and twenty-five adult patients representing about 300 children for examination. We can only accomplish this by limiting ourselves strictly to the children of positive cases, and having them brought singly for examination.

Of the treatment given our regular patients, a few words will suffice. It differs in no essential respect from that employed by all the special workers in this field. The earliest cases are always sent, if possible, to the best available sanatorium, for that initial training in the habit of living which can best be taught under sanatorium supervision. Upon their discharge, they are referred back to us for further observation and control. Our advanced and destitute cases are also placed, as promptly as pos-

sible, in a suitable hospital, both for their own care and for the protection of others. These are the patients, practically hopeless in prognosis, who are the greatest source of danger to their families and neighbors: for a person in an advanced stage of pulmonary tuberculosis is usually too weak or too ill to know or care how he disposes of his sputum, and he often expectorates millions of tubercle bacilli a day.

It is a regrettable fact that the hospital and sanatorium facilities in and around New York City, for either advanced or early cases of tuberculosis, are utterly inadequate to the demands made upon them. I refer, of course, to the charitable institutions, since we are dealing with the city's poor. We aim to place most of our early, and all of our advanced, cases in suitable institutions where they can be properly segregated, and receive the care best adapted to their respective conditions. Practically we are able so to dispose of only a small proportion of our patients. All the second stage, or moderately advanced, cases—we follow the classification adopted by the National Association for the Study and Prevention of Tuberculosis—all of any stage, whom we are unable to send away for any reason, and all those patients who have been at sanatoria and are sent back to us, are under our immediate care. They are required to report every week at the Dispensary, where they receive advice, instruction, and such medication as may be indicated.

We are obliged to employ medication to a greater extent than is desirable or necessary from the purely therapeutic point of view, since the low average of intelligence among our patients necessitates the use of drugs in control of the symptoms for which they seek relief. Tonics, laxatives, various formulæ for the relief of cough, hemoptysis or night-sweats, and occasional sedatives, diuretics, and intestinal antiseptics, make up the list of our usual remedies. A dozen formulæ, of the simplest nature, would practically comprise them all. We are, of course, occasionally obliged to treat adventitious symptoms or intercurrent diseases.

The chief feature of our treatment lies in the persistent training in daily hygiene, and our insistence upon the three chief factors in all successful management of the disease—oxygen, feeding, rest. In addition to our verbal instructions, we give printed circulars, in the different languages, which are supplied to us by the Board of Health, to all patients able to read or comprehend them. In this way, the educational part of the work is carried on in the homes of the patients, and each of our cases becomes a focus in the tenements for the further dissemination of simple and accurate information about consumption, its cause, its prevention, and its cure.

The Board of Health renders us invaluable assistance in many ways, three of which seem to me of primary importance in the general crusade—the registration of new cases, the examination of sputum, and the disinfection of premises occupied by tuberculous cases. As soon as a case has been diagnosed as positive, it is reported by our nurse to the Board of Health; and upon the death or transfer of any of our cases, the Board of Health promptly and thoroughly disinfects the room, or rooms, occupied by the patient. By the assistance of the Board of Health, too, an unmanageable patient can be forcibly committed to a suitable hospital. To other refractory, but less dangerous cases, we can refuse treatment and the additional nourishment, in the form of milk and eggs, of which we can supply a limited amount of selected cases.

Of the results of such treatment, under the conditions which I have described, I would say, in general terms, that within nearly five years we have received and treated over 1,200 pulmonary cases, the majority of which were tuberculous, and most of them moderately or far advanced. That these patients were derived, for the most part, from the poorest and most unintelligent class in the city, and are living in the worst possible environment for the successful treatment of the disease. We have been able to send a certain number of them to suitable sanatoria, to the country, or back to their homes in Europe. We have cared for the great majority in their own homes, the tenements of the most congested district of the world, meeting the individual conditions as best we could, and, by verbal instruction, printed information, and home supervision, constantly teaching and reiterating the lessons of personal hygiene and prophylaxis. We have been able to report a dozen or more "cured" and "apparently cured"—following, again, the classification of the National Association—among the patients who have been two or more years under our observation, and we have a very considerable number of "arrested" cases whose symptoms are under control and whose physical signs are not progressive. It is fair to state that a majority of our cases improve under treatment, as might be expected from the improvement in their mode of life. A certain number of advanced or susceptible cases, usually among the alcoholics, are steadily and rapidly progressive, terminating fatally within a few weeks or months. We illustrate, at Gouverneur, what I have already said of the special clinics in general. We treat many cases; we cure a few, arrest the progress of the disease in many, and teach them all.

In conclusion, I would earnestly call your attention to the fact that whereas we are, in New York City, dealing with a problem of tremendous size and vast civic importance, no community, however small or however ideally situated, is wholly free from the universal scourge of tuberculosis; and however few and isolated the cases, each is a danger to that community. From a single such neglected spark may spread a vast conflagration. One single case of consumption, in city or country, is one case too many. If we are wise in our day and generation, if we heed the fearful lessons of the carelessness or the ignorance of the past, we will undertake, in every county of the State, and in every town and hamlet, to adopt, and adapt, the methods for the extermination of tuberculosis now employed with such signal success in New York City.

129 East Seventeenth Street.

EUPYREXIA.*

By CAMILO CALLEJA, M.D.,

MADRID.

The aim of this clinical study is to increase our knowledge, as yet slight, regarding pretuberculosis, with which natural immunity comes into such close relation.

I call this pretuberculous fever "eupyrexia," this word meaning good fever, by antonomasia, that is, the best of all fevers, a disease almost exclusively belonging to youth and children. The inquiry into this affection is very interesting since it gives us a clear account of the generation of tuberculosis, and also because it is the base upon which we establish the scientific principles regarding the prophylaxis of this disease.

*Paper read in Section 1 of the Sixth International Congress on Tuberculosis, October 1, 1908.

This is an infection in which we must consider accurately the two factors: the internal, that is the state of the constitutive cells of the body, and the external, the medium in which the cells live. In regard to the eupyrexia, the two factors are: (1) a deficiency of the constitutive oxygen of the cells of the body; this deficiency I denominate hypoxygenia; and (2) a superabundant proliferation in the body of the saprophytic tuberculous bacteria, which I call Ferran's bacilli.

Hypoxygenia, that is, the lack of reoxygenation in the organism, may be either primary or secondary. Primary hypoxygenia is a general asthenia due to imperfect breathing and an insufficient intake of oxygen, so that there is an imperfect compensation of the oxygen we constantly lose. Secondary hypoxygenia may be either general or local; the former is at times caused by chronic infections like lues, or chronic intoxications like alcoholism, sometimes by primary anemia resulting from poor alimentation; and also it may be produced by a dyscrasia especially when the individuals are narrow-chested (dolichosomatous). Local hypoxygenia may be produced by traumatism and also by an idiosyncrasy; this is generally inherited from ancestors suffering from sclerotic diseases, among which nicotinism, besides the disease before mentioned, is one of the most important. In secondary hypoxygenia, the want of oxygen in the system is the result of the tissues having lost some of their power of reoxygenation on account of their presclerotic state. Complex hypoxygenia is that in which the primary and secondary forms are combined in the same subject.

Sufferers from chronic hypoxygenia are predisposed to pretuberculous affections, one of which is eupyrexia; but germs are indispensable to the development of tuberculosis. These germs, which are Ferran's bacilli, are non-acid-fast, are somewhat similar to the *B. coli communis,* and can be transformed into Koch's bacilli and *vice versa.* Besides, they determine by inoculation tuberculous processes. As Koch's bacilli can scarcely live outside the pathological tissues or in places exposed to air and sunlight, while Ferran's bacilli are almost everywhere, to these we must impute the beginning of pretuberculosis and consequently of eupyrexia.

Once Ferran's bacilli invade the tissues they produce an infection, which, like all infections, is a real fecundation (and not merely the sowing of a seed as is generally believed). The pretuberculous infection begins by nervous alterations; then if the stimulus of Ferran's germs continues hyperemia is determined; afterwards the congestion, instead of remaining local, may become general and pretuberculous fever or eupyrexia is produced. In addition to this the local process may advance further, developing into an inflammatory process and later on, special granulations—which I call euphymia (that is good growth)—may be formed. To sum up, there are five degrees of pretuberculous affections: Neuroses, hyperemias, fevers, inflammations, and granulations. Moreover, there are complex pretuberculous affections in which two or more of the elemental ones, which I have just mentioned, are united. To understand what is pretuberculosis and the place euphymia has in the process, we have to consider that the five different affections we have mentioned are like five correlative degrees of the same process, and that everyone of the first four pretuberculous affections may either prevent or cure the following ones. That is to say, pretuberculous neuroses, hyperemias, fevers, and inflammations may be preventive processes of the pretuberculous granulations, and may be their curative process once they have appeared. For this reason, the first four pretuberculous affections I call "antiphymias"; the eupyrexia being an antiphymic fever capable of preventing or of curing pretuberculous granulations, and even phymatosis really tuberculous, that is, having already Koch's bacilli. Again, Ferran's bacilli, by provoking pretuberculosis, are usually the natural cure for hypoxygenia, but in case of the latter being too intense, and the tissue being greatly degenerated, instead of hypoxygenia being resolved the process becomes tuberculosis properly co-called; because the degenerated tissues feed Ferran's bacilli with noxious products which change them into Koch's bacilli. We consider true tuberculosis only that condition in which we find both tuberculous tissues and Koch's bacilli.

Eupyrexia is a very important and frequent disease, especially in young people, and is manifest in different forms, but the principal may be reduced to four: (1) Pseudotyphic eupyrexia, which is the most typical. Belonging to this variety are many of the cases hitherto diagnosed as intestinal infections, without specifying the cause; also many other fevers qualified as attenuated typhoids, and a great number of catarrhs of the digestive organs considered as grippal. (2) Pseudorheumatic eupyrexia, to which belong many of the cases generally qualified as rheumatic fevers since, in my opinion, young people who are growing rapidly, when they suffer from long and irregular fever with pains in their limbs, without noticeable local swelling generally suffer from eupyrexia. (3) Pseudopneumonic eupyrexia, which is marked by symptoms of congestion of the respiratory organs like bronchitis, transitory pneumonia, and, when it lasts long, sometimes has the appearance of an incipient consumption. (4) Pseudopaludic eupyrexia, to which belong almost all paroxysmal fevers which are not malarial and are neither septic nor pyemic. I will add a few details regarding the diagnosis of the typical or pseudotyphic variety, which generally begins with one or more ephemeral pyrexial attacks similar to those produced by moderate malaria; then follows a remittent fever increasing gradually like typhoid, but the general state of the patient, even after many weeks, does not present the characteristic symptoms of typhoid, this being the principal difference, that in euphymia the patients have neither the appearance nor the feeling of being ill.

With this and the antecedents, we can often reach a differential diagnosis; but it is not infrequent to see cases which are not diagnosed until a long time after having been cured, and the diagnosis is then established by some other pretuberculous or tuberculous manifestations presenting themselves. Surely, before long, with the advance of serum-diagnosis, with the establishment of the opsonic index and other similar tests, we shall be able to recognize pretuberculosis from its beginning.

In pretuberculosis, as in all pathological processes, we must differentiate the bad effect of the causes of the disease from the good vital reaction of the organism. Regarding eupyrexia, hypoxygenia is the bad process, while the fever or general reaction provoked by Ferran's bacilli is the eubiotic or curative process. Unless this distinction be clearly understood, one will fall into the error of attacking every symptom the patient presents; and from the failure of the practitioner to make this distinction arises the frequent abuse of sedative therapeutics in neuroses, hyperemia, fever, inflammation, and new growths, although all these are nothing but the different degrees of the curative process. Eupyrexia

in particular produces most beneficial results. Hence we must respect the fever, considering all antithermics contraindicated. We must further consider that, as Ferran's bacilli are the stimulants of vital reaction in pretuberculosis, we must not attack such germs, because, then, we unarm nature of her most valuable therapeutical recourse.

The only efficacious treatment is to combat hypoxygenia, our efforts being directed especially to its prevention. The method must be different according to whether the hypoxygenia is primary, secondary, or complex. For all alike, pure air is the best treatment, but the results are very different, being more marked in primary hypoxygenia.

Besides the chief indication, there are some vital ones, like those which arise from collapse and hemorrhages, which are to be treated as in any other disease. We must say the same regarding the repair of loss of substance and the restoration of the strength of the patient; nevertheless it is well to advise not to follow the old saying, "starve a fever"; on the contrary, when the first week of the fever has passed (during which it will be well to restrict the diet somewhat), we must give as much and as nutritious food as the patient can digest, so that the calories, which the fever consumes, may be made up. But it often happens that the digestive organs cannot do as much work as is necessary; then, we must prescribe some preparations to help the metabolism, so that the bacilli become less virulent and the sufferer may resist the disease. For this purpose we may prescribe the phenol derivates, the arsenicals, one of the colloidal forms of silver, and organic preparations such as tuberculin, always taking care to use them in small doses, as in eupyrexia they merely produce a stimulating effect upon the cells.

We must keep in mind that there is not, nor ever will be, a specific against eupyrexia; that the remedies proposed, and all those that may be recommended in the future, will be no more than palliatives, and that we must only employ resources which favor the vitality of the cells, without attacking Ferran's bacilli.

Spain offers to the pretuberculous the most favorable climates to be found anywhere. In summer, on heights like Panticosa and seaside places like La Toga; and in winter, the mountains around Malaga, Almeria, and Alicante.

The definite prognosis of eupyrexia, that is, that judgment regarding the results of treatment, confirms, at least for the present, our assertion as to the limited influence of the therapeutic means at our disposal. The prognosis is uncertain, since the fever is seldom influenced by medical treatment. I do not pretend to have done more in attending eupyretic patients than to increase their resisting powers.

In conclusion: Our first aim in eupyrexia must be to prevent hypoxygenia; but, once this is produced, eupyrexia is its best natural or spontaneous curative process. Hence we must help the development of eupyrexia in those suffering from hypoxygenia, for which pure air is the best recourse. Whether he breathes or does not breathe sufficient pure air may determine whether the individual suffers from eupyrexia or from consumption. Consequently, in addition to the direct preventive influence of atmospheric air, recognized by all as a means against tuberculosis, we have described here another preventive effect which, although indirect, is of great value, and is exercised by means of the pretuberculous process which I denominate eupyrexia. This knowledge regarding eupyrexia gives rise to an optimistic conception of pretuberculosis, since, in my opinion, most cases of pretuberculosis, chiefly the eupyrexias, are substutive processes, which act favorably on asthenic states, thus preventing the danger of cachexia and producing this natural immunity.

EARLY MEDICAL SCHOOLS AND LEGAL REGULATION.*

By JAMES J. WALSH, M.D., Ph.D., LL.D.,

NEW YORK.

DEAN AND PROFESSOR OF THE HISTORY OF MEDICINE AND OF NERVOUS DISEASES, FORDHAM UNIVERSITY SCHOOL OF MEDICINE.

At this first semi-annual meeting of the medical faculty, since it is to be the custom to present a subject connected with medical education at each meeting, it seems not inappropriate to begin with some account of the first medical school of which we have any definite knowledge. The phase of its history that shall occupy us is the uplift of professional status and dignity that it brought about in the course of time. The first formal school of medicine was at Salerno, and probably came into existence during the ninth century. We do not know as much about this as we would like to, though we have many of the books written by its most famous professor, Constantine Africanus. We know in addition the rather startling fact that there were women professors, for women's diseases, and that these were distinguished in their specialty. We have certain works written by several of them, and especially the text book of Trotula, who taught in the eleventh century. The idea thus suggested of co-education near ten centuries ago, and of women physicians in good standing, is extremely interesting.

The surprising thing is how much about medicine that we are apt to consider quite modern was anticipated a thousand years ago at Salerno. For this we have not the authority of vague tradition, but the actual works written by professors of Salerno. We are not interested, however, so much in the question of medical science as of medical education. As a consequence of the high standard of medical education reached at the University of Salerno a corresponding evolution in professional dignity took place, and the rights of physicians were secured by legal regulations that are extremely interesting because they represent the securing by these colleagues of ours seven hundred years ago of legal regulations such as we have been striving for for the better part of a century, and have only succeeded in attaining in recent years. As a matter of fact it is not too much to say that we have not yet reached quite the standard of professional education which was required by law in the early part of the thirteenth century in the country of which Salerno was the representative medical university.

The only way to make this statement very clear is by presenting the documents in the case. The most important of these is the famous law of Frederick II., who was the King of the two Sicilies, as the southern part of Italy and the Island of Sicily were called, and who afterward became the German Emperor. This law, often referred to by medical historians, has only recently been published in its entirety by Robert Ritter von Töply, the well known Viennese historian of medicine. In this, Emperor Frederick lays down very definitely three propositions that are almost startling in their modernness. First the student of medicine must have

*Paper read before the first semi-annual meeting of the Medical Faculty of Fordham University School of Medicine, December, 1907.

three years preliminary study in a university. Second he must study medicine for five years, and then practise only under the direction of a physician for a full year before beginning to practice himself. If he wishes to practise surgery he must study anatomy for a year in addition to this. Third he must exercise great care with regard to the drugs that he prescribes and see that the druggist supplies them in all their purity. Various regulations are added for the druggist, making this the first pure drug law.

Of course Frederick would not have issued such a law only that the conditions of the time and the professional status already secured by physicians had not only justified, but demanded it. Usually such a law is the result of the long-continued efforts of well-known medical men to secure rights for themselves and their colleagues. It seems not unlikely that Frederick, who was a magnificent scholar with the widest possible interests, had been closely in touch with a number of distinguished physicians in his kingdom, and allowed them to draft a law regulating all the practice of medicine and of pharmacy, and then had formally issued it, or else had used their suggestions for drawing it up. With this in view it is easy to understand the paragraphs of the law which show such a startling anticipation of the attainment of what physicians have been trying to secure for the last twenty-five years, and which we have not entirely succeeded in obtaining even yet.

Frederick's law opens with a paragraph in which he declares his interest in the health of his subjects, and how much that is dependent on the proper medical education of their physicians. This reads much more like the preamble of a set of resolutions passed by some modern medical society in order to tempt a State Legislature to give them a proper law regulating the practice of medicine, than the first paragraph of a legal regulation of medicine in the first half of the thirteenth century. "While we are bent on making regulations for the common weal of our loyal subjects we keep ever under our observation the health of the individual. In consideration of the serious damage and the irreparable suffering which may occur as a consequence of the inexperience of physicians, we decree that no one in future who claims the title of physician, shall exercise the art of healing, or dare to treat the ailing, except such as have beforehand in our University of Salerno passed a public examination under a regular teacher of medicine and been given a certificate, not only by the professors of medicine, but also by one of our civil officials, which declares his trustworthiness of character and sufficiency of knowledge. This document must be presented to us, or in our absence from the kingdom, to the person who remains behind in our stead in the kingdom, and must be followed by the obtaining of a license to practise medicine either from us or from our representative aforesaid. Violation of this law is to be punished by confiscation of goods and a year in prison for all those who in future dare to practise medicine without such permission from our authority."

Frederick then proceeds to lay down the terms of the requirements for medical education. The most interesting feature of these is the fact that a student had to have a preliminary education of a noteworthy amount before being allowed to enter upon the study of medicine. Besides this he must practise under a physician for a year before taking up independent practice for himself. The latter part of the requirements that he shall have devoted special attention to anatomy if he wishes to practise surgery is an open contradiction to much of what has been said about the neglect of anatomy during the Middle Ages. Here in a formal document, however, is the best evidence for interest in this study in this time.

"Since the students cannot be expected to learn medical science unless they have previously been grounded in logic, we further decree that no one be allowed to take up the study of medical science without beforehand having devoted at least three full years to the study of logic.*

After three years devoted to these studies he (the student) may, if he will, proceed to the study of medicine, provided always that during the prescribed time he devotes himself also to surgery, which is a part of medicine. After this, and not before, he will be given the license to practice, provided he has passed an examination, in legal form, as well as obtained a certificate from his teacher as to his studies in the preceding time. After having spent five years of study he shall not practise medicine until he has, during a full year, devoted himself to medical practice with the advice and under the direction of an experienced physician. In the medical schools the professors shall, during these five years, devote themselves to the recognized books, both those of Hippocrates, as well as those of Galen, and shall teach not only theoretical, but also practical medicine.

"We also decree as a measure intended for the furtherance of public health that no surgeon shall be allowed to practise unless he has a written certificate, which he must present to the professor in the medical faculty, stating that he has spent at least a year at that part of medicine which is necessary as a guide to the practice of surgery, and that, above all, he has learned the anatomy of the human body at the medical school, and is fully equipped in this department of medicine, without which neither operations of any kind can be undertaken without success nor the injured be properly treated."

Other paragraphs of this famous law are concerned with the legal requirement that the physician must wait upon the poor whenever summoned, without charge, and it announces what the maximum charge shall be. Considering the buying power of money the legal fees were about what they are at the present time. That is a man was allowed to charge from ½ tarrene to one tarrene, equivalent to about one to three dollars in our money, unless he went out of town, when he was allowed also to add his expenses and nearly to double his fee. There was a very curious element in the legal regulation of the fees, however, inasmuch as a physician was required to charge by the day, and not by the visit, and he must decide how many visits the patient needed each day. Under ordinary circumstances it was declared that he must see a patient twice a day.

In the light of recent developments in legislation, State and national, perhaps the most generally interesting feature of the law is that which makes it the first pure drug law of which we have any record. Every physician was required to take an oath that whenever it came to his knowledge that any apothecary had for sale drugs that were less than normal strength he should report the matter to the court. Other paragraphs relating to drugs run as follows:

"In every province of our kingdom which is under our legal authority, we decree that two prudent and trustworthy men, whose names must be

*Under logic at this time was included the study of many of the subjects that are now taken up in the arts departments of our universities. Huxley declared the college education of this time better than our own.

sent to our court, shall be appointed and bound by formal oath, under whose inspection electuaries and syrups and other medicines be prepared according to law and only be sold after such inspection. In Salerno in particular we decree that this inspectorship shall be limited to those who have taken their degree as masters in physics.

"Stations for the preparation of medicines may not be located anywhere but only in certain communities of our kingdom as we prescribe below.

"We decree also that the growers of plants meant for medical purpose shall be bound by a solemn oath that they shall prepare their medicines conscientiously according to the rules of their art, and so far as it is humanly possible that they shall prepare them in the presence of the inspectors. Violations of this law shall be punished by the confiscation of their movable goods. If the inspectors, however, to whose fidelity to duty the keeping of the regulations is committed, should allow any fraud in the matters that are entrusted to them, they shall be condemned to punishment by death."

There is scarcely a feature of our modern progress in the regulation of medical education and professional practice that is not contained in this law of the early part of the thirteenth century. It is amazing, of course, to find it, and yet it shows only what is a very common occurrence in history, that supposed progress is really only a reestablishment of conditions that obtained long ago. The most interesting thing in history, indeed, and quite the most difficult to understand is how men having gained certain advantages for which they have long striven then allow themselves to lose them because of a certain complacency that comes over them and keeps them from devoting as much attention to maintaining what they have gained as they did to gaining. It is a surprise to be told that probably the Suez Canal, or at least a waterway connecting the Mediterranean with the Red Sea, was opened long ago, remained open for several centuries, and then was allowed to fill up. It is only a striking symbol, however, of what happens with regard to many human advantages. It seems impossible that we should ever again lose what we have gained in the matter of medical education and regulation and yet the lesson of history illustrates the possibility of it and shows that only diligent attention to the maintenance of rights will conserve them.

INTERPRETATION OF BLOOD EXAMINATIONS.

By IRA S. WILE, M.S., M.D.,

NEW YORK.

CLINICAL PATHOLOGIST CHILDREN'S DEPARTMENT VANDERBILT CLINIC.

Incorrect interpretations of hematological results have been sufficient to retard and discredit hematological work. There are many factors which tend to prevent blood examination from assuming its proper place among routine clinical procedures. The unsettled state in which hematology finds itself at present is due to the few years that have been given to its careful study and to the fact that at the present time instruction in hematological technique and interpretation is insufficient for practical application.

The mixed nomenclature is also a factor in preventing many practitioners from following the literature of the subject. Men trained in the classification of Ehrlich become confused when reading of differential counts wherein the nomenclature employed is that of Cabot or Da Costa or Wood. There is a lack of harmony because various observers have hit upon different characteristics of the leucocytes to be utilized for purposes of classification. The hematologists themselves should unite in determining upon a uniform nomenclature. The variety of instruments of precision, the differences in technique of staining, and the dogmatic statements regarding the value of each, place the general practitioner in a quandary and do not simplify blood work nor arouse any great enthusiasm for it.

For clinical work it suffices to group all the lymphocytes under one head. Whether they are called lymphocytes or mononuclears is of no practical importance. The myelocytes are mononuclear but characterized by distinctive granulation. The relative variations of the lymphocytes are contrasted usually with the percentage variations of the polynuclear neutrophilic leucocytes. It is this contrast which possesses immense practical diagnostic and prognostic value. The varieties of the polynuclear leucocytes are the neutrophile, the eosinophile, and the basophile. Every practitioner should be able to differentiate the above five types of leucocytes.

Another valuable point which is widely overlooked is the value of knowing what are the relative percentages of leucocytes during the first ten years of life. The statement that some case of abscess failed to show an increase of neutrophiles is especially common when cases of children are reported. To give an example of this error I shall quote from a recent article by a most excellent and careful otologist on "the clinical value of the differential blood count in operative otology." "In three cases there was nothing to explain a high temperature and marked prostration except the presence of a discharge from the patient's ear. There were no other symptoms or physical signs. The ages of these patients were respectively six months, fourteen months, and two years. . . . In this series of three cases the lowest polynuclear proportion was 42.4 per cent., and the highest 56.8 per cent., and from this the natural deduction would be absence of sepsis, but in relation to this low polynuclear proportion was a marked decrease in the number of white cells usually found. The white cells as found were respectively 7,000, 9,000, and 11,000 in round numbers. . . . In talking with Dr. Sondern about the lack of confirmatory evidence as shown by the differential blood count, he advised operation, saying that when the resistance of the patient was steadily decreasing, as shown by the small number of white cells, it was just as important to operate, if not more so, than where the polynuclear percentage was high. Following his advice I operated and found an abundance of pus in the mastoid process in each of these cases. For several days following these operations, a differential count was made, the result being a rather rapid increase in the white cells, showing an increased resistance of the patient, but no material change in the polynuclear percentage took place until after the fourth day, when there was a drop of several points *below what is usually estimated as the normal standard* (italics mine). Particularly was this noticeable in *one case where the polynuclear proportion prior to operation was 42.4 per cent. In this case five days after the operation a differential count showed a polynuclear proportion of 36.6 per cent. The age of this patient was 14 months. Why such a discrepancy existed* in these last cases I am unable to explain, unless it be that owing to their low body resistance, the usual rapid absorption of pus

did not take place." There is no discrepancy here. The normal polynuclear percentage at fourteen months is 36 per cent., and 42.4 per cent. at this age indicates an increase of the polynuclears.

Too much stress cannot be placed upon the necessity of being familiar with the normal variations in percentages of lymphocytes and polynuclear neutrophiles at various ages. The table of averages in normal children I have found to be as follows, agreeing very closely with the results of Karniski and Carstagen.

Age.	Polynuclear Neutrophiles.	Lymphocytes.
1	35%	53%
2	38%	51%
3	42%	47%
4	47%	41%
5	52%	39%
6	52%	37%
7	53%	35%
8	54%	33%
9	55%	31%
10	60%	30%

The interpretation of the appearance of myelocytes requires careful discrimination. The significance of myelocytes in children is far less serious than in adults.

From the viewpoint of interpretation, the relation between the total leucocyte count and the relative percentage of polynuclear neutrophiles is of the utmost importance. In general terms, the percentage of polynuclear neutrophiles is the relative index of intensity of infection. The total leucocyte count is an index of individual reaction to infection. Thus a high leucocyte count (40,000) with low polynuclear percentage (70 per cent.) is less serious than a low total leucocyte count (9,000) with a high polynuclear percentage (95 per cent.). This is especially valuable in the interpretation of blood examinations in surgery.

But even this close relation must not be abstractly considered. Hematology offers a wonderful diagnostic agent but not *per se* a diagnosis. The only exception to this is in conditions like malaria, filariasis, etc., wherein a parasite is manifest only in the blood. The greatest error and most serious drawback to hematological work among general practitioners has been their expectation of a short cut to diagnosis through blood examination. A complete blood examintion does not make a diagnosis. It does, however, yield most valuable information regarding the effect the pathological process has upon the blood. In other words blood examination determines an important symptom. Blood examination only elicits symptoms. The symptom must be interpreted in the light of the entire clinical history and not as an isolated fact.

The gastrologist does not diagnose gastric ulcer from hyperacidity of the gastric juice. The mere presence of sugar in a specimen of urine does not make certain a diagnosis of diabetes mellitus. The presence of albumin in the urine does not establish a dignosis but offers a none the less valuable symptom. The entire history of the case is necessary for the diagnosis. Frequent analyses may be necessary. Blood examinations may require repetition. Their interpretation can be correct only when they are considered a part of the history of the case.

Corroborative symptoms are very important. The Widal reaction is not essential to a diagnosis of typhoid fever, but its presence is corroborative. The temperature course may suggest typhoid fever. The blood picture of a leucopenia and lymphocytosis may suggest typhoid fever. The presence of the three symptoms makes the diagnosis certain. The diazo reaction in the urine still strengthens the correctness of the diagnosis. But the diagnosis of typhoid fever cannot be made from any single one of these tests. Nor will one examination for each of them, when negative, determine the nonexistence of typhoid fever. The diazo reaction may be present in tuberculosis or measles. The leucopenia and lymphocytosis may exist in grippe or even in diphtheria. The sum total of symptoms establishes the clinical identity of a disease. Clinical hematology is a necessary adjunct in determining symptoms.

Considerable attention has been given to diagnosis from stained blood smears. Again must caution be observed lest a wrong interpretation arise. Differential counting of leucocytes establishes a symptom which may strengthen or weaken a tentative diagnosis. Lymphocytosis is present in pertussis, but finding a lymphocytosis does not mean the presence of pertussis. The rest of the clinical history is essential. Eosinophilia is a most prominent symptom of trichiniasis but eosinophilia is not diagnostic of trichiniasis any more than it is of bronchial asthma or urticaria. Hemorrhage is often accompanied by basophilia, but a diagnosis of hemorrhage would not be made merely from basophilia. Punctate basophilia is common and intense in plumbism, but it is frequently found in rachitic anemia.

No diagnosis, save of parasites, should be based simply upon a blood examination. Even the declaration of an anemia as a primary pernicious anemia is impossible from a blood examination. An anemia of the pernicious type is a safe statement. The pernicious type of anemia may follow rachitis, or typhoid fever, or infection by *Bothriocephalus latus*, or syphilis. These pernicious anemia types are clearly secondary and may clear up entirely. Many anemias may be at present cryptogenetic, but it is very doubtful if any are primary. The term "primary anemia" will become obsolete with the advance of etiological study.

The diagnosis of leukemia from the examination of a blood smear is not always possible. A leukemic type of blood picture may exist in diphtheria and even after a fracture (Simon). The whole clinical history determines the correct diagnosis.

Hodgkin's disease is another example of the necessity of this point of view. If a diagnosis were made by an examination of the blood, the patient with Hodgkin's disease would be normal as the blood picture is unchanged. In other words Hodgkin's disease presents no hematological symptom. The rest of the clinical picture is very similar to that of leukemia but the latter has hematological symptoms. Hodgkin's disease should not be classified among diseases of the blood. During the course of the disease a varying degree of anemia may occur, no more characteristic however than the secondary anemia arising in the course of sarcomata.

Let hematology be considered a clinical adjunct as urine analysis and interpreted as rationally. When the general practitioner recognizes the true position of blood examination and appreciates the necessity of careful interpretation of his hematological findings, the value of blood examination will be enhanced and its range of usefulness widened.

A CONTRIBUTION TO THE SUBJECT OF SYPHILITIC PROPHYLAXIS BY THE USE OF CALOMEL OINTMENT; REPORT OF A CASE.

By ABR. L. WOLBARST, M.D.,

NEW YORK.

ATTENDING GENITOURINARY SURGEON, BETH ISRAEL HOSPITAL AND WEST SIDE GERMAN DISPENSARIES; PROFESSOR OF GENITOURINARY DISEASES, NEW YORK SCHOOL OF CLINICAL MEDICINE.

In May, 1906, Metchnikoff reported to the Academy of Medicine of Paris, that he and Roux had at last succeeded in discovering what they felt sure was a prophylactic against syphilitic infection. This announcement was made in the paper entitled "Some New Facts Concerning Experimental Syphilis," and the principal feature of interest in the paper was the report of the experimental inoculation of a medical student with syphilitic virus fresh from an indurated chancre. This was followed an hour later by the application of calomel ointment (calomel 1 part, lanolin 3 parts) to the site of the inoculation, carefully rubbed in for five minutes.

Control experiments made with the same virus at the same time upon one chimpanzee and four monkeys (Java macaques), gave undoubted proof of the specific virulence of the virus. The chimpanzee and two of the monkeys were inoculated simultaneously with the student, but were not treated with the ointment. Of these, the chimpanzee died several days later of pneumonia, without showing any effects of the inoculation, and the monkeys developed a typical syphilitic lesion seventeen days after the experiment. Two monkeys were treated with the ointment. In one of them it was rubbed in for five minutes, one hour after the inoculation. This monkey showed no signs of syphilitic infection forty-one days after the experiment; in the other, the ointment was applied twenty hours after the inoculation, and at the end of 39 days a primary lesion of undoubted character developed. These control experiments showed that in monkeys at least, the ointment, if applied an hour after inoculation, prevented infection.

The student was under careful observation from February 1, the date of the inoculation, till May 31, on which date Dr. Roux, after a most thorough examination, declared that there were not the slightest traces of syphilis to be found, and that therefore the experimental application of the calomel ointment as a prophylactic measure in man was to be regarded as successfully demonstrated.

A careful study of the details of the experiment leaves much to be desired before its results can be accepted as positive proof. For instance, we have no way of telling what would have been the result if the same virus had been inoculated in another human being, without the ointment being applied. Would he have developed syphilis? It is manifestly unsatisfactory, to place implicit confidence in the result of an experiment made on man, the control being made on monkeys. Nevertheless, until such control can be made on man, we shall have to be content with the monkey control.

Secondly, how are we to know that the student who was inoculated would have developed syphilis if the ointment had not been employed? We see every day in our practice men who for years have had sex relations with lewd women who must surely be syphilitic (and gonorrheic, as well), yet they seem to bear a strong immunity against the infection. How do we know that this student does not enjoy immunity against syphilitic inoculation?

In spite of these unanswerable questions that suggest themselves, we are surely justified in feeling that the experiments of Metchnikoff and Roux have brought us considerably nearer than we have ever been to a means of preventing syphilitic infection.

When, therefore, an opportunity presented itself some months ago to apply the experiment in actual practice, I seized the opportunity, and herewith present a report of the same. The conditions under which the experiment was made were as nearly ideal as it is possible to have them in practice, though the result can hardly be said to be altogether convincing.

About five o'clock of the morning of May 2, 1908, I was awakened by a man who demanded immediate advice and treatment. The patient, A., was a young man, 22, single; previous health good, and positively of a negative venereal history, which a general examination confirmed. It appears that A. and a friend, B., had spent the night with a woman, who, they discovered later by her own admission, was suffering from active syphilis. Both men had copulated with the woman several times during the night, and the chances of infection were as good as they could possibly be.

A. wanted me to do something for him; he was engaged to be married and threatened suicide if the disease showed itself. His friend B. had hurried away to catch a train for the West. I told A. that I knew of nothing that would surely prevent infection, but I would apply an ointment that might possibly do so. At the worst it would do him no harm. Thus within six hours after his first exposure he had applied the calomel ointment (30 per cent. strength in lanolin), rubbed in for five minutes wherever there was any possibility of inoculation. I directed him to repeat the inoculation every four hours, until he had used up all the ointment (30 grams). I also advised him to bring the woman to me for confirmation of the diagnosis. I saw her several hours later, and found the apposing surfaces of the labia majora covered with isolated and coalescing papules, some of them as large as a cent. Around the anus was a group of condylomata lata, typical in appearance, and on the tongue and buccal membrane were specific ulcerations that could not be mistaken for anything else.

For three weeks A. reported to me ever other day, with negative result. On June 3 (32 days after exposure) he brought with him his friend B., who had just returned from the road. B. exhibited a typical indurated chancre on the coronal sulcus, which was followed in a few weeks by an unmistakable papular eruption, which, together with the primary lesion, soon disappeared under mercurial treatment. A. has visited me at least twice every week throughout this period of more than four months, and he is apparently as free from syphilis as he ever was.

Of course this report is intended as a simple contribution to the interesting and useful subject of prophylaxis, not as a confirmation of Metchnikoff and Roux's experimental work, though it might be considered as such. We have here these ideal conditions: Simultaneous and repeated exposure by two young men, to the same syphilitic virus. One man receives prophylactic treatment six hours after exposure and escapes the disease; the other is not treated, and develops typical lesions which in due time respond to antisyphilitic measures, thus acting as a control to the first.

Question 1. Would A. have been infected as B. was if the ointment had not been used?

Question 2. Would A. have been infected if the ointment had been used twenty-four hours after exposure?

105 East Nineteenth Street.

A NEW, SIMPLE, AND READY METHOD OF DROPPING ETHER FROM THE ORIGINAL CAN.*

By JOSEPH E. LUMBARD, M.D.,
NEW YORK.
ANESTHETIST TO THE HARLEM HOSPITAL; FORMERLY ANESTHETIST TO MOUNT SINAI HOSPITAL; FELLOW NEW YORK ACADEMY OF MEDICINE, ETC.

The drop method of administering ether is to-day interesting a greater number of surgeons and anesthetists than ever before. Numerous dropping bottles, as well as dropping devices to be inserted into the can, have been contrived, but I believe that valid objections can be raised against all of them to which the method about to be described is not open. One objection to a special bottle is that it is not advisable to remove a good ether, for use as an anesthetic, from the original tin to another container, lest thereby it absorb moisture or become contaminated otherwise. An objection to any particular contrivance to be attached to the can is that such is an extra piece of apparatus, which may not be at hand or may be out of order when it is wanted, while, further, both special bottles and droppers are a continual extra expense.

Fig. 1.

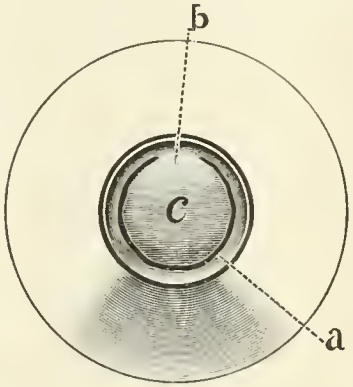

Fig. 2.

My method of dropping ether requires no special apparatus, therefore it involves no extra cost. Moreover, I have found it is at all times easy to manage and fulfilling perfectly the end desired. Furthermore, I believe it to be original with me, for by a careful searching of libraries I cannot find it either pictured or described; and the opinion of those who ought to know about such things and whom I have consulted is that it is a new idea.

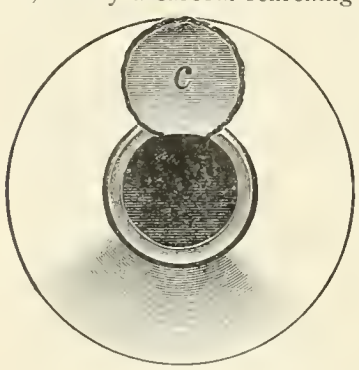

Fig. 3.

This new way of dropping ether is as follows:

1. Make a circular incision through the soft metal cap (Fig. 1, *c*) of the can, as close to the edge of the neck as possible. Extend this about four-fifths of the way around (Fig. 2, *a*), leaving the flat or center portion of the cap (*c*) attached to the neck for the remaining one-fourth or less of its circumference (*b*).

2. Turn this flap (*c*) back, taking care not to detach it or to crack its connection with the outer rim of the cap still attached to the neck (see Fig. 3). The danger of separation is not great, but as this flap will possibly be of use for a second anesthesia, all unnecessary to and fro movement should be avoided.

3. Insert a small pledget of absorbent cotton which has been twisted previously into a sort of wick into the neck and as far up into one angle of the incision as possible, and then turn down the flap (*c*) to its original position (see Fig. 4). This will then hold the wick (*d*) tight in the neck.

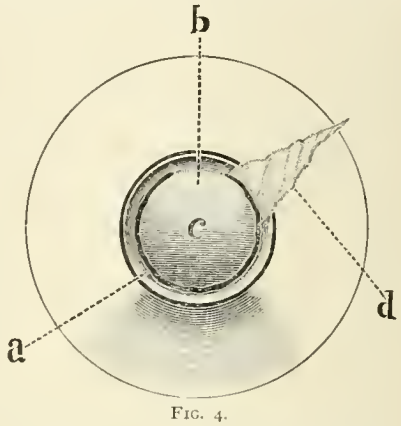

Fig. 4.

4. The can of ether is now ready for use, and if it be tilted, holding it so that the detached side of the flap is uppermost (Fig. 5), drops of ether will fall from the end of the wick, rapidly or slowly according as the can is tilted much or little. The size of the drops also can be regulated by manipulation of the wick. If the cotton be twisted to a fine point, the drops will be small. If the end of the wick be made blunt, the drops will be large. If, moreover, it is desirable to pour ether from the can, the top need not be disturbed; simply rotate the can so as to bring the middle part of the incision downward, *i.e.* the part not plugged by the wick, and when the can is tilted ether will flow out freely.

Fig. 5.

5. If, after using, some ether remained in the can, the flap (*c*) can be folded back again as in Fig. 3 and a cork put into the neck, which will perfectly prevent the escape of ether from the can, yet leave the soft metal flap in a condition for use in a subsequent induction of anesthesia (See Fig. 6).

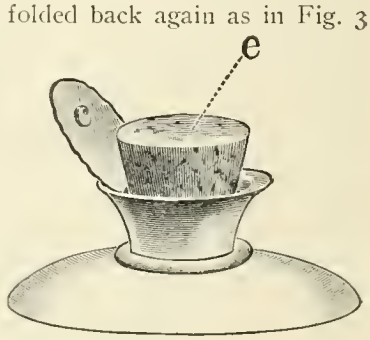

Fig. 6.

The advantages of this method of dropping ether are availability, simplicity, and cleanliness. It costs nothing, it leaves the purity and strength of the ether undisturbed, and, if it is properly managed, it will not be possible to deluge the mask or the patient's face.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, October 24, 1908.

HUNTINGTON'S CHOREA.

THE Germans have a very laudable custom of honoring men who have won distinction in scientific or practical medical work by issuing special publications, the so-called *Festschrifte,* to which the pupils of the worker to be honored or other authors contribute special articles. Here in America similar publications have been appearing within recent years, one notable one having been issued in honor of Dr. Welch of Johns Hopkins University. The second number of *Neurographs,* a new periodical devoted to neurological studies, answers a similar purpose by considering the work of Dr. George Huntington formerly of Long Island, who in 1872 brought the subject of hereditary chorea of adults to the attention of the medical world. Dr. Huntington comes from a family of physicians, both his grandfather and father having practised medicine in Easthampton, Long Island. It was their observations of the peculiar nervous disease which existed in that neighborhood that helped the young physician, only one year after his graduation from a medical college, to write a classic description of the disease which has since become known as Huntington's chorea. This account is worth quoting *in extenso*: "The *hereditary* chorea, as I shall call it, is confined to certain and fortunately a *few* families, and has been transmitted to them, an heirloom from generations away back in the dim past. It is spoken of by those in whose veins the seeds of the disease are known to exist, with a kind of horror, and not at all alluded to except through dire necessity, when it is mentioned as 'that disorder.' It is attended generally by all the symptoms of common chorea, only in aggravated degree, hardly ever manifesting itself until adult or middle life, and then coming on gradually but surely, increasing by degrees, and occupying years in development, until the hapless sufferer is but a quivering wreck of his former self." Dr. Huntington then describes the three marked characteristics of the disease; its peculiar hereditary nature, for if it ever skips a generation it never manifests itself in another; the tendency to insanity of suicidal nature that often attacks the victims of the disease; and finally, its coming on only in adult life, without ever showing any manifestations of its presence before the age of thirty or forty years.

The statements as to frequency of this peculiar disease are quite varied. Thus M. Allen Starr states that he has never observed a case. On the other hand Adolph Strümpell, in an article reprinted in this issue of *Neurographs,* writes that he has seen about half a dozen cases; Sinkler reported several cases in 1889 and again in 1892; while Hamilton collected and reported twenty-seven cases of the disorder in the *American Journal of Insanity* for 1908. The affection has received much attention since Huntington's paper, being a fascinating one for study, not only from the scientific interest it has for the medical profession, but also because of the fatal and tragic character of its transmission in the families affected, an "heirloom from generations away back in the dim past." To anyone, therefore, inclined to look into the history and nature of this affection that approaches so nearly the character of the "evils" of olden days, the "Huntington number" of the *Neurographs,* with the bibliography compiled by the editor, Dr. William Browning, will prove of great value and interest. To the busy man of the profession, toiling, perhaps, far away from great centers of medical teaching, Dr. Huntington's work, in the small Long Island town, must prove a source of personal inspiration in the study of the material afforded him by his practice.

THE SANITATION OF MINES.

THERE are certain diseases which are peculiarly prevalent among miners. The affection known as miners' phthisis is one of these, while ankylostomiasis is another troublesome and not infrequently deadly malady to which the man who works underground is subject. The latter complaint is due to a large extent to defective and inadequate sanitary arrangements, as proved by the fact that it is in mines in which the conditions are unhygienic that ankylostomiasis chiefly flourishes. Uncinariasis, the term now preferred to ankylostomiasis, was first clearly described by Dubini in 1843, and is stated by Sandwith to have been mentioned by the old Egyptian writers three or four thousand years ago. The disease was afterwards found among the tunnel workers of St. Gothard, since which time it has beeen generally recognized as a leading cause of tropical anemia, and of miners', brick-workers', and tunnel-workers' anemia.

Cases have occurred, indeed far more often than has been believed, in our Southern States, and the parasite has been and is still largely responsible for the many instances of anemia happening among a certain section of the southern white population. Uncinariasis was first made definitely known to the American medical public by the report on anemia in Porto Rico published by the Porto Rico Commission, just after the Spanish-American war. It has been found in the mines of Pennsylvania and is fairly common in the Philippines. Oliver, an English physician who is one of the greatest authorities on diseases incidental to miners, has stated that the miners of Westphalia suffer greatly from the inroads of the hook-worm, while Haldane has shown that the anemia of the Cornish miners was due to the same cause.

Dr. Frank Shufflebotham read a paper dealing with the sanitation of mines before the Industrial Hygiene Section of the Royal British Institute of Public Health, at Buxton, on July 21. Among other interesting points bearing upon the disease he drew attention to the fact that only a certain

percentage of those infected with the parasite show symptoms. This is of great importance because they are just as great a menace as those whose symptoms are marked. A high temperature is favorable to the spread of uncinariasis, while moisture is an essential factor for the development of the ova and the growth of the larvæ, and lack of sanitary arrangements aids in its dissemination.

Typhoid fever is another disease which can be and is frequently spread in mines by the want of efficient sanitary methods. Dr. Shufflebotham suggests that there should be proper conveniences at the pit bottom and at convenient points near the main roadways where large numbers of men work. By the evidence given a short time ago in England before the Royal Commission on Mines it was shown that in some districts there was an entire lack of sanitary arrangements underground, and Dr. Shufflebotham is of the opinion that it should be made compulsory for all mine owners to make suitable sanitary provisions at each colliery.

It has been said that uncinariasis is not prevalent to any extent in the coal mines of this country, but it is probably more common than is generally believed. It would be interesting also to collect figures in regard to the frequency of typhoid fever occurring in American mines. There can be no doubt that unless proper closet provision is provided mines will lend themselves favorably to the propagation of that disease. At any rate, it must be in the best interests of health that sanitary arrangements in mines should be as perfect as possible.

THE PATHOGENESIS OF CIRRHOSIS OF THE LIVER.

While it is generally admitted that cirrhosis of the liver is caused by the toxic character of the portal blood, the nature of the toxin being different in the various types of the disease, there are several features of the pathological anatomy of a cirrhotic liver which the acceptance of this hypothesis leaves unexplained. The essence of the disease consists, of course, in the well known diminution of the highly specialized liver cells and the increase of the connective tissue of the organ; the latter phenomenon which was long held to be the primary factor of the disease by reason of the compression it exercised upon the secreting cells of the liver, is now generally regarded as a secondary event, the connective tissue simply proliferating after the secreting cells have been injured or have disappeared, the term "replacement fibrosis" very well expressing the process that takes place. The strange part of the cirrhotic process consists in the very unequal distribution of the fibrosis throughout the organ, large islands of liver tissue being perfectly preserved and evidence of hyperplasia and hypertrophy being present, parallel with the total loss of all functionating epithelium in other areas.

This is the problem considered by Dr. Ribbert in the *Deutsche medizinische Wochenschrift* for September 24, 1908. The fact that uniform degeneration of the liver substance takes place in phosphorus poisoning and similar conditions speaks against any differences in the susceptibility of the various portions of the liver to toxins and, therefore, it must be supposed that in cirrhosis the toxins do not reach all parts of the organ uniformly. Of course a bacterial origin of cirrhosis could explain these differences in the amount of injury to the organ, for infectious processes very seldom involve an organ uniformly. In some cirrhoses, such as those of syphilis, for instance, the unequal distribution of the lesions is explained by the microbic nature of the process, but the great majority of cirrhotic processes are toxic in origin and other explanations are required. The simple experiment of passing variously colored fluids through the veins composing the portal system gives the clue to the explanation, for it is found that the various streams mix but little while on the way to the liver. Any toxin dissolved in the blood of the veins is accordingly unevenly distributed throughout the organ, the angular branching of the portal vein serving to keep the streams apart on reaching the liver. Now, it is probably true that the toxic substances in the portal blood are derived from the upper gastrointestinal tract where absorption is most active; the spleen is in itself a detoxicating organ while in the colon absorption is not so active as in the small intestine, although of course cases may occur in which the blood reaching the liver from the spleen or the pancreas may contain toxic substances. In the majority of cases, however, the distribution of the cirrhotic process is about the same as the distribution of variously colored solutions passed to the liver through those branches of the portal vein which drain the upper gastrointestinal canal. The ultimate nature of the process, that is, the specific toxins causing the disease must be sought by a careful comparison of the various areas affected in the different types of cirrhosis with what is known of the formation or absorption of toxins in the parts of the gastrointestinal system drained by the branches of the portal vein which supply these areas.

GIFTS AND ENDOWMENTS.

The gift of Mr. Frederick Cooper Hewitt to the Post-Graduate Hospital is conspicuous for something more than mere size. Too often has it occurred in the past that donors to educational institutions holding in mind some fixed hobby or extensive project have restricted and hampered the usefulness of the bequest, and virtually have bound hand and foot those who are responsible for its preservation and adaptation. Not so Mr. Hewitt. The $2,000,000 is given to the institution subject only to the condition that it be formally accepted and used to further the interests of medical science.

One of the chief difficulties experienced by college presidents and boards of trustees is that of manipulating the amounts of money at hand so that a given department shall be developed equally with every other. In a great university, any university one is tempted to say, funds are constantly being proffered, and of necessity accepted, which instead of lightening the burden of debt really increase it. For instance, the department of law already well equipped may be offered a sum of money to found a chair of this or that special subject, while the departments of medicine or theology go begging and have a struggle to hold up their heads and main-

tain their existence. It is obvious that such a gift can work little benefit to the institution in question, inasmuch as the new department is not needed, and hence is likely to be slighted both by the incumbent occupying the chair and by the students. With all due respect to the multimillionaire who is willing to bestow his wealth upon institutions of learning, his peculiarities as to the distribution of his alms sometimes approach the ridiculous. For example, a gentleman offered a well-known university in a neighboring State $200,000 for the erection of a huge gateway upon a certain spot on the campus, provided the gates should always be kept closed. As the site demanded was a valuable one for dormitory purposes the trustees were obliged to decline the gift with thanks and wait for a wiser and more considerate head to furnish funds for the dormitory.

But to come back to the more immediate question of the medical school, there is no institution, speaking generally, which is in greater need of certain fixed endowments. The medical school of largest possibilities must be located in a great city where the cost of location and erection of suitable buildings is tremendous. But this is not all—there is the equipment of laboratories with electrical and chemical apparatus; there are the sums needed for insurance, coal, light, attendants, teaching staff, all of which makes the annual aggregate sum that must be provided very great indeed. Fees received from students do not at all provide for these expenditures. The medical school is in consequence always in need of help from its affiliated university, which is in turn very often hard pressed for the maintenance of its purely academic curriculum. It is quite obvious, therefore, that gifts which cannot be used to defray current expenses are likely to prove cumbersome if not unwelcome.

Diagnosis of Tuberculous Bronchopneumonia in Children.

Tuberculous bronchopneumonia is a disease that is engrafted upon simple bronchopneumonia, developing secondarily as a result of the presence of tuberculous tracheobronchial glands. The earliest lesions are those of the tracheobronchial glands, but the occurrence of a simple bronchopneumonia is a signal for the transference of the tubercle bacilli from these glands to the pulmonary substance, and the continuance of the acute malady under a new form which renders the usually good prognosis absolutely bad. For this reason the diagnosis and the differentiation from simple bronchopneumonia becomes of importance. G. Mouriquand, writing in the *Gazette des Hôpitaux* for August 1, 1908, discusses the differentiation of this condition. Of physical examination methods inspection, palpation, and percussion give no information whatever. It is only by auscultation that we obtain the peculiar physical sign of this disease which is the occurrence of crepitant or subcrepitant râles in any portion of the pulmonary tissue. Any other râles may be the result of simple bronchitis or pneumonia. The dyspnea and cyanosis now have a special character. Instead of an urgent dyspnea there are substituted a rapid respiration and a dyspnea that is well borne by the little patient. The glands of the neck and axillæ become painlessly enlarged, so as to resemble small peas rolling under the finger. Laboratory methods give no added information. The condition of the patient grows steadily worse, cachexia becoming marked, and death ensues after a time from generalized tuberculosis. Had the patient been suffering from simple bronchopneumonia the dyspnea would have been gradually relieved, the temperature would have fallen, and the lungs would have gradually cleared of all signs with the return of good health.

Serum Treatment of Lobar Pneumonia.

There have been attempts made for some years to treat lobar pneumonia by means of sera, but we can have, seemingly, no specific serum against the disease, since there are several different organisms which may cause it. We recognize, however, that from each arises a condition of intoxication that affects the nervous system, heart, kidneys, and other organs. This universal toxemia must be prevented by some means. The greater or lesser diffusion of the anatomopathological process does not depend alone upon the number and virulence of the bacilli, but upon the extent of intoxication of the bulbomedullary nervous centers. We must reduce this intoxication and increase the powers of defense against the toxins. Talamon has proposed to neutralize these poisons by the use of antidiphtheritic serum, which increases the phagocytic power of the organism and increases the formation of antibodies. In pneumonia caused by pure diplococci the use of antipneumococcic serum is of value, and when there are mixed infections with streptococci present, antistreptococcus serum of the polyvalent variety may be used. To be of value any of these sera must be used in the first days of the disease, before intoxication of profound degree has taken place. E. Farroni, writing in the *Gazzetta Medica di Roma*, for August 15, 1908, gives the results of his experience in the treatment of this disease by sera. He finds that the temperature is reduced, the severity of the disease is lessened, the heart action is bettered, the sensorium becomes clearer, and the whole course of the disease is shortened. There are no bad effects from any of these sera, and none of them affects the kidneys badly. His choice of sera is influenced by the form of germ that is found to exist in the given case. He advocates a resort to orrhotherapy in all cases of pneumonia as being more rational than the old-fashioned course of heart stimulants and expectorants.

Pharyngeal Neuroses.

Pharyngeal paresthesia is a symptom that may cause an entire misconception of a patient's physical condition. A trivial lesion of the pharynx, or no lesion at all, combined with a nervous predisposition may bring about a diagnosis of tuberculosis of the throat. In some cases the presence of paresthesia, causing difficulty in swallowing, ends in a refusal of food by the patient, or a severe dry cough, emaciation, and bad general condition result which simulate tuberculosis. There is present a sensation of a foreign body in the throat, of obstruction, or of pain. Maurice Boulay and H. le Marchadour, writing in the *Tribune Médicale*, of September 5, 1908, assert that there may be a true hallucination of a sensorial nature referred to the pharynx, a peripheral projection of a purely mental image. In other cases, as a result of the vitiation or the exaggeration of a slight sensation in the throat there is a real pharyngeal illusion. The nervous predisposition may be hereditary or acquired, but it is always present. The

suffering that the patient experiences is out of all proportion to the lesion that may be found in the throat, which is often a very small ulceration. This neurosis may be slight in form or so severe as really to endanger life from refusal to take food. In these cases the element of fear and anxiety plays a prominent part. The treatment of this unfortunate condition is mainly mental and suggestive. To tell these patients that there is no basis for their sufferings is worse than useless. We must acknowledge their reality at the same time that we give them the best hopes of an entire and early cure.

News of the Week.

First Harvey Society Lecture.—Prof. A. Calmette, Director of the Pasteur Institute of Lille, France, will deliver the first lecture of the course at 8:30 p. m. on Saturday, October 24, at the Academy of Medicine. The subject of the lecture will be, "Intestinal Infection and Immunity in Tuberculosis." Dr. Calmette will speak in French, but printed translations of the lecture will be available for those who may desire them.

Public Health Exhibits.—The Public Health and Marine-Hospital Service has announced plans for an interesting exhibit of modern hospital apparatus, methods of treatment, and laboratory appliances, at the Alaska-Yukon-Pacific Exposition, which will be held in Seattle in 1909. The exhibit will include a model operating room, thoroughly equipped, with wax figures placed as if an operation were in progress, and a hospital section showing a record room and model ward. The laboratory section will contain apparatus, glassware, sterilizers, microscopes, microphotographic apparatus, etc., for general laboratory work, and will include a traveling laboratory, two of such outfits being constantly held in readiness by the Service for field work, and for use in the event of outbreaks of epidemic disease in various parts of the country. A model of the Marine Hospital Sanatorium for tuberculosis at Fort Stanton, New Mexico, will be shown; and the quarantine section will include a model of a detention camp, and of a quarantine station. A complete *x*-ray apparatus will also be exhibited.

Health of the Canal Zone.—The report of the Department of Sanitation of the Isthmian Canal Commission for the month of August, 1908, shows a steady improvement in the sanitary conditions. Comparing the past three years the figures are as follows: August, 1906, number of whites, 5,269, number of deaths, 8, death rate, 18.22 per thousand; August, 1907, number of whites, 11,733, number of deaths, 17, death rate, 17.38; August, 1908, number of whites, 12,607, number of deaths, 10, death rate, 9.52. Among the negro employees the decrease in the death rate is even more striking, and forms the most noteworthy item in the report. The figures are as follows: August, 1906, 24,286 employees, 145 deaths, death rate per thousand, 71.60; August, 1907, 27,710 employees, 76 deaths, death rate, 31.76; August, 1908, 31,618 employees, 32 deaths, death rate, 12.14. The exceptionally high death rate for August, 1906, was largely due to a severe epidemic of pneumonia among the negroes; in August, 1905, the rate was 35.93. The sick rate is considered to be the best measure of the average effectiveness of the force so far as they are affected by the health conditions. In 1906, among every thousand of employees 42.67 were sick every day; in 1907, 29.02 and in 1908, 25.24. There have been no cases of yellow fever or of plague originating on the Isthmus in the past two years. In 1906, there were 9 deaths from typhoid fever among employees; in 1907, 7 deaths; and in 1908, no deaths. The decrease in deaths from dysentery was also marked. In 1906 there were 10, in 1907, 6, and in 1908, 2.

Tuberculosis Exhibit Prizes.—The award of prizes for the best exhibits at the International Congress on Tuberculosis at Washington, was announced on October 11. Germany received a gold medal for the best exhibit sent by any country exclusive of the United States, illustrating effective organization for the restriction of tuberculosis. Silver medals in this class were presented to Sweden and Great Britain. New York won a gold medal for the best State exhibit, silver medals going to Massachusetts and Pennsylvania. The gold medal for the best exhibit showing the most efficient laws and ordinances in force on June 1, 1908, for the prevention of tuberculosis in a municipality was awarded to New York City, Saranac Lake ranking second, and Chicago third. The best exhibit of State laws and ordinances was made by Wisconsin, which received the gold medal. Maryland and New York received silver medals. A prize of $1,000 for the best evidence of effective work in the prevention and relief of tuberculosis by any voluntary association since the last Congress, was divided between the Women's National Health Association of Ireland, and the Committee on Tuberculosis of the Charity Organization Society of New York City. The Henry Phipps dispensary of Baltimore received a prize of $1,000 for the best exhibit of a dispensary for the treatment of tuberculosis. Gold medals in this competition were voted to the Manhattan tuberculosis dispensary of the New York Department of Health and to the dispensary of the Henry Phipps Institute of Philadelphia, and a silver medal went to the dispensary, Clemmente Ferreira of San Paulo, Brazil. The Brompton Hospital of London won the $1,000 prize for the best exhibit of a hospital for the treatment of advanced cases. A special gold medal was awarded to the United States Bureau of Animal Industry for the best pathological exhibit, and the exhibit from England also received a gold medal. The exhibit from Massachusetts showing devices to improve sanitary conditions in factories was given a silver medal, and a special gold medal was presented to the United States Government Printing Office for sanitary cuspidors and other appliances. Gold medals were also awarded to the New York State Charities Aid Association, for effective work in organization, to the Sea Breeze Hospital, to the Colorado Fuel and Iron Company, for its hospital and welfare department, and to the Children's School Farm League of New York. The New York State Committee received a silver medal for its exhibit illustrating the production of clean milk, and honorable mention was made of the Nathan Strauss exhibit. Arthur C. Chapman of West Orange, N. J., a sufferer from tuberculosis, also received honorable mention for a model of a shack built by himself, in which he had lived in his backyard, with considerable improvement in his condition, and by which he desired to show what a poor man could do to help himself to recovery.

The Legal Standing of an Osteopath.—That an osteopath may sign a death certificate and that the Department of Health must register osteopaths as physicians, is the decision handed down by the Court of Appeals on October 13, in the case of Charles F. Bandel of Brooklyn, former president of the New York State Osteopathic Society. Dr. Bandel signed a death certificate of one of his patients and the Department of Health refused to file

it, with the result that a coroner was called in to the case. Dr. Bandel thereupon obtained a preemptory writ of mandamus from the Supreme Court ordering the Department to accept the certificate. The case was carried through the Appellate Division to the Court of Appeals, the decision in each court being against the Department of Health.

Hospital in Hotel.—An emergency surgical hospital, the first of its kind in the city, has been opened in a basement room of the Waldorf-Astoria, New York, near an all-night drug store. A complete outfit for emergency surgery has been installed, and Dr. C. T. Adams and Dr. Robert Adams have been placed in charge.

Death Rate in New York.—The weekly mortality tables for the five boroughs of Greater New York for the week ending October 10, show that the death rate is lowest in the more thickly populated portions. Thus in Manhattan, the death rate was 13.67 per thousand for this week, while in Richmond the mortality was 19.05. For the corresponding week in 1907, the rate was 15.84 in Manhattan, and 27.95 in Richmond. For the entire city the rate was 14.43 for 1908, and 16.36 for 1907. The bulletin shows a marked increase in the number of cases of scarlet fever and diphtheria.

The New York City Training School for Female Nurses held its thirty-third annual commencement on October 17 at the Nurses' Home on Blackwell's Island. Diplomas and prizes were presented to thirty-nine nurses, who represented nearly as many countries and States.

Typhoid Bacilli Carrier.—An epidemic of typhoid fever in Georgetown, S. C., has been traced to a woman who runs a dairy farm in Maryland, and who suffered an attack of typhoid fever eighteen years ago. Although in perfect health, as in other of these strange cases of "bacilli carriers," she was found to be infected with the germs to an extraordinary degree. Thirty cases have thus far appeared, and of these twenty-six used milk supplied by this dairy.

Measures to Guard Against Contagion.—On October 9, the Chief of Police of Chicago issued a general order directing the commanding officers to instruct their men that the warning cards of the Health Department were not to be torn down, and also that infected children were to be kept off the streets. This order was issued largely on account of complaints made to inspectors of the health department that the police were not giving sufficient support to the employees of the Health Department in enforcing quarantine in contagious diseases.

Public Care of the Insane.—Dr. Adolph Meyer, in an address delivered at the Conference of State Charities, of Illinois, outlined a program of asylum reforms, internal and external, which the State Board of Charities will profitably use as a basis for its own campaign for adequate legislative appropriations and enabling measures. He insisted on high standards, on efficient organization, on prevention, as well as intelligent after-care of patients, and on co-operation with the State and its appointees of the medical profession and public-spirited citizens.

Lake Forest Hospital Formed.—Application was recently made for a certificate of incorporation for the Lake Forest (Ill.) Hospital. Already a fund for the erection of the building is in the hands of the Board. Real estate valued at $2,500 was bequeathed to the hospital by J. B. Farwell; $3,000 was appropriated by the city; $2,500 was realized by the annual horse show, and $820 from the Lake Forest Day Celebration of the Woman's Club.

Charitable Gifts.—The Presbyterian Hospital of New York has just received a gift of one million dollars from its president, Mr. John S. Kennedy, on the occasion of the fiftieth celebration of his marriage. Mr. Kennedy has previously made large donations to the work of the hospital, in which he has been interested for many years. It is understood that his latest gift is to be used for construction purposes.

By the will of the late Mrs. Hartman Kuhn of Philadelphia, Harvard University receives $175,000 to endow a department of biological chemistry, in memory of the testator's son. The Massachusetts General Hospital also receives $10,000 to establish a clinic laboratory.

Suit for Large Fee.—A homeopathic physician of Philadelphia has entered suit against a Pittsburg steel magnate for the collection of a bill for $20,000 for special services rendered at the rate of $500 a visit. The physician was summoned from time to time to make visits to his wealthy patient at short notice wherever he might be.

Special Clinics for School Children.—The Throat, Nose and Lung Hospital has established special clinics for school children at 3:30 p. m. daily. This hour has been fixed so that school duties may not be interferred with.

Death of a Centenarian.—Miss Sarah Morse, who celebrated her one hundredth birthday on September 29, died at the Methodist Home in Brooklyn, on October 11. She was born in Albany, but had passed most of her life in Brooklyn, where she supported herself by sewing up to the time of her admission to the Home eighteen years ago.

Dr. Henry A. Christian was elected Dean of the Faculty of the Harvard Medical School, on October 14. Dr. Christian is professor of the theory and practice of medicine, and is a graduate of Johns Hopkins Medical School. He is but thirty-two years old.

Dr. C. Ward Crampton was elected Director of Physical Training on October 14, by the Board of Education of New York, to succeed Dr. Luther H. Gulick who recently resigned to accept a position with the Sage Foundation. Dr. Cramptom has been connected with the physical training work in the public schools since its inception, and has for some time served as assistant director. He was graduated from the College of Physicians and Surgeons in 1900

Street Car Accidents.—The report of the Public Service Commission for September permits for the first time of a comparison with the report of last year, the Commission having completed in August its first year of work. The report shows a decrease in the number of those killed by street car accidents from 63, in 1907, to 34 in 1908. The number of less serious accidents has, however, increased from 216 to 310. By far the largest number of injuries are caused when alighting from cars.

The New York Pathological Society.—At a regular meeting of the Society on October 14, the president, Dr. E. Libman, read a paper prepared by Dr. Wolff-Eisner of Germany, which the author had been prevented by illness from presenting at the International Congress on Tuberculosis, on "Theoretical and Practical Considerations Concerning the Significance of the Conjunctival Reaction (Ophthalmo-Tuberculin Test)." Dr. Wolff-Eisner, who was present, also addressed the Society, and the paper was discussed by Dr. P. Courmont of France. A

number of interesting specimens and cases were also presented to the Society. At the next meeting, on November 11, Dr. W. T. Longcope of Philadelphia, is to be the guest of the Society, and in December it is planned to hold a combination meeting with the Surgical Society.

The Manitoba Medical Association held its first meeting for the purposes of organization on October 8, at Winnipeg, at which nearly one hundred physicians were present. The following officers for the new society were elected for the ensuing year: *President,* Dr. J. R. Jones, Winnipeg; *Vice-President,* Dr. J. A. McDonald, Brandon; *Second Vice-President,* Dr. J. R. McRae, Neepawa; *Secretary,* Dr. Jasper Halpenny, Winnipeg; *Treasurer,* Dr. R. W. Kenny, Winnipeg; *Executive Committee,* Dr. Hicks, Griswold; Dr. Ross, Selkirk; Dr. Keele, Portage la Prairie; Dr. Speechley, Crystal City; Dr. Harrington, Dauphin; *Auditors,* Dr. Blanchard and Dr. Moody, Winnipeg.

The Holyoke (Mass.) Medical Society at its annual meeting on October 6, elected the following officers: *President,* Dr. G. L. Gabler; *Vice-President,* Dr. T. E. Cavanaugh; *Secretary and Treasurer,* Dr. I. H. Farr; *Executive Committee,* Drs. J. H. Potts, G. L. Taylor and J. J. Carroll.

Medical Reserve Corps, U. S. A.—Commissions have been issued to the following Philadelphians as first lieutenants: Drs. John B. Deaver, Francis D. Patterson, J. Chalmers da Costa, Edward Martin, John G. Clark, Hobart A. Hare, George E. de Schweinitz, J. William White, Charles B. Pensrose. The commissions carry no salary, but they render the recipient available for instant service in case of war.

The Eastern Medical Society of the City of New York has completed arrangements for a dinner and reception to be held on Thanksgiving night, November 26, at the Hotel Astor. The society has an active membership of over five hundred.

The National Association for the Study of Epilepsy and the Care and Treatment of Epileptics will hold its eighth annual meeting at Indianapolis, Ind., on November 10 to 11, 1908. The president of the Association is Dr. H. M. Weeks of Skillman, N. J., and the secretary, Dr. J. F. Muson of Sonyea, N. Y. The objects of the Association are to promote the general welfare of sufferers from epilepsy, to stimulate the study of the causes and methods of cure of the disease, to assist in establishing a proper system of care for epileptics, and to advocate the care of epileptics in institutions designed to meet their special needs. As this is the first time the Association has met in the West, it is hoped that there will be a large attendance.

American Association of Railway Surgeons.—At the annual meeting of this Association, held in Chicago, October 14, 15 and 16, the following officers were elected for the ensuing year: *President,* Dr. J. R. Hollowbush, Rock Island, Ill.; *Vice-Presidents,* Dr. Benjamin Thompson, Tama, Ia.; Dr. G. W. Thompson, Winamac, Ind.; Dr. Oscar Le Seure, Detroit, Mich.; *Secretary-Treasurer,* Dr. H. B. Jennings, Council Bluffs, Ia.; *Editor,* Dr. Louis J. Mitchell, Chicago.

The Late Dr. Holt.—The following resolutions have been adopted by the American Electro-Therapeutic Association:

Whereas, Death has removed from our numbers Dr. John D. Holt of Berlin, N. H., an energetic and industrious physician, beloved by all who knew him, be it

Resolved, That we extend our profound sympathies to his wife and family in their bereavement in which the Association participates, and

Resolved, That a copy of this resolution be sent to the family of the deceased, and also for publication in the Official Organ of the Association, in the Medical Record and in the *Journal of the American Medical Association.*

(Signed.) Edward C. Titus, M.D.,
President.
J. W. Travell, M.D.,
Secretary.

Obituary Notes.—Dr. James S. King of Brooklyn, N. Y., died on October 9, at his home, aged 54 years. Dr. King was graduated from the Long Island College Hospital in 1878, and was one of the founders of the Bushwick Hospital, a member of the Brooklyn Pathological Society, and surgeon of the Naval Reserves.

Dr. Francis Alfred Gile of Bloomfield, N. J., for twenty-five years a leading practitioner of the Oranges, died on October 12, at his home, from heart failure following a severe attack of kidney trouble, aged 63 years. Dr. Gile was graduated from the New York Homeopathic College in 1875, having previously served throughout the Civil War in the 165th New Hampshire regiment. He was a member of the State Homeopathic Society and of the American Institute of Homeopathy.

Dr. John Eberle West of Jersey City, N. J., died on October 14, of dilatation of the heart, aged 65 years. Dr. West was graduated from the Ohio Medical College in 1867, and had practiced for forty years. He was president of the Hudson County, New Jersey, Board of Health and Vital Statistics, and a member of the Board of Pensioners.

Dr. Charles Franklin Rand of Washington died at his home on October 13, at the age of 63. Dr. Rand answered the first call for troops when the Civil War broke out, distinguished himself in several battles, received a medal of honor, and was promoted to a captaincy. After the war he studied medicine at the Georgetown Medical College.

Dr. John E. Parsons of Ayer, Mass., died at his home on October 9, aged 72 years. Dr. Parsons was a graduate of the Harvard Medical School, and served as a surgeon during the Civil War.

Dr. George A. Elliott of New York, a graduate of the New York University Medical School in the class of 1892, and visiting physician to the Fordham Hospital, died on October 15, at Glen Cove, L. I., aged 41 years. Dr. Elliott was for several years connected with the New York Department of Health.

Dr. Herbert Russell of New York died on October 14, aged 37 years. Dr. Russell was graduated from the Long Island College Hospital in 1896.

Dr. Howard B. Neiman died at Philadelphia on October 15, at the age of 24 years, as the result of ingestion of aconitin in mistake for a cough mixture. He was graduated from Jefferson Medical College in the class of 1906, and for two years had been resident physician in the Philadelphia Home for Incurables.

Dr. H. W. Bartscher of St. Louis, Mo., died on September 28, after a stroke of apoplexy while testifying in the Probate Court, aged 49 years. He was a graduate of the St. Louis Medical College, and had also studied abroad for several years.

Dr. George R. Fisher of Olneyville, R. I., died on September 30, after having been in ill health for more than a year, aged 55 years. Dr. Fisher was graduated from New York University Medical College in 1875, and served for sixteen months as interne at Bellevue Hospital, New York.

Correspondence.

MEDICINE IN VENICE.

To the Editor of The Medical Record.

Sir:—You receive interesting letters from various important medical centers of the world. A letter from Venice will have this distinction, that it comes from a place renowned in history, but quite without any medical past—or present. Venice used to be a great place for plagues, but these were treated as visitations, to be removed by prayer, not sanitation. Vesalius lived here a little while, and the Venetian press printed many of the medical books written by the men of Padua. This is its medical past, or all I can learn of it. Venice cultivated commerce and art—not science. Venice is a city of nearly 200,000 people, but it has no medical school, no public medical library, few laboratories, and no effective medical organization like our academies and county societies. It has but one hospital—the Ospedale Civile. I must qualify all this a little. Venice sends her students to Padua, which is only an hour away, and there is still at this university the medical school, with good men attached. The city has a Health Department, and Dr. Monti, in charge, has a laboratory and is a good bacteriologist, sanitarian, and pathologist. In the Ospedale Civile there is also a laboratory with a competent pathologist, Dr. Jona, and the hospital has a medical library. In the famous Bibliothek of St. Mark there are also some old medical books. The Venetians are great sticklers for isolation and disinfection when they wake up and find the case. So they have set aside an island in the lagoon for contagious diseases, including tuberculosis and typhoid. And up to a short time ago if one were "denounced" to the authorities as having either of these maladies off he was sent to this place. Recently there has been organized an English, or cosmopolitan hospital, under English management and support, and certain of the milder infections can be taken there. But the Italian seems to prefer to neglect or ignore infection until it is no longer possible to do so, and then to attack it with a mixture of the ferocity of the past and the science of the present. The result is that the medical men are not inclined to report infections like typhoid and tuberculosis—at least this is my information.

The city hospital already referred to occupies the old guild house of San Marco and the Dominican monastery. It has a beautiful façade and a magnificent carved ceiling in one of the great wards. It has some excellent physicians and surgeons attached, but its general management seems along lines of about thirty years ago. It has no system of trained nurses, the wards are mostly of enormous size, and overfilled with beds lined up in many rows.

History blanks hung on the wall by each bed. I looked at some. The notes were as meager as those in certain New York hosiptals when the interne thinks he is overworked. Though the wards are crowded, the ceilings are so high that the air space is probably not so small as seems at first sight. Everything looks very clean and orderly, despite the lack of nurses. Apparently the Italians do not take to nursing, partly perhaps on account of the expense; but the young women will not go into it and the people and doctors do not appreciate its value. When ill they get their medicine and food and take it or not, as may be, leaving the rest to the saints. The traveler, however, who falls by the way can usually get trained nurses through the local medical men.

Among the Italian physicians Professor Vitelli, formerly pathologist at the University of Bologna, and now physician to the City Hospital, is perhaps the leading consultant, and he is a very competent man, of sound judgment, and an excellent diagnostician. Professor Giordano is, I am told, the leading surgeon, and a very skillful one.

One of the famous physicians of Venice, Dr. Fritz Keppler, died last spring. He was known to many Americans and was an unusual and interesting personality. He was very active and successful professionally both as surgeon and physician. He had a private polyclinic and did an enormous amount of work for the poor, by whom he was greatly beloved. He held no public hospital positions. This city, I am assured, is in the hands—and feet and teeth of the clericals—every material interest except the hotel business seems to be controlled by them. Dr. Keppler was fond of letters and the arts and left a wonderful library of some 20,000 volumes which I have had the privilege of examining. It is equally rich in the most modern and most ancient medical treatises, besides a collection of the classics.

During the last months of his long final illness he devoted his time to writing an essay on "Copa," a Latin poem ascribed to Virgil.

The only English physician here is Dr. Van Someren, a skillful man, of sound medical training and wide experience. He has done laboratory work in connection with the subject of nutrition and metabolism, and is working at problems of this kind now.

Dr. Heppich, who is an English speaking German, is a young man with the best kind of German university training. He was an assistant in surgery and gynecology at Marburg, but he is also thoroughly trained in internal medicine and is a good clinical pathologist.

I am writing of these things at some length, partly perhaps because I have received so much kindness here, but also because Venice in summer is almost an American city; much more than half the visitors at the hotels seem to be from the United States. If one falls ill in a hotel in Europe, as some know, the chances are that he gets a native doctor who has to pay the management or the portier a percentage; and the patient may or may not get skilled service. The hotel managements of Europe like to have what they term "a good hotel doctor," which means some one who orders expensive rooms and plenty of service, a not too quick recovery entailing suitable fees. This is no exaggeration of the actual state of things. It may not be any worse in Europe than in America, and it does not apply here in the very best hotels, perhaps. As for the Italian physicians, I can best quote what Vellari says in his book entitled "Italian Life in Town and Country" (1902): "The profession whose members stand highest for respectability and skill is that of medicine. Medical tuition in Italian universities is inadequate and unsatisfactory; the number of medical degrees is enormous (over 1,000 per annum) and out of all proportion to the needs of the population; the remuneration for medical and surgical attendance is very small; yet, in spite of all these disadvantages, Italian medical men are among the best in Europe."

It will be seen that if Venice is no medical center it has good doctors and sufficient resources in private hospitals to take care of the sick and injured wayfarer. The nurses have to be imported as a rule, but it is possible to get very good ones.

Venice has been in the past a plague-smitten city. This was due partly to the fact that the commerce and travel of the East and West passed through it, and partly to the malarial surroundings and the bad habits of life, including the use of wells. Venice is surrounded by small islands and mud-flats. The salt water of the Mediterranean was mixed with the fresh water of three not very large rivers which emptied here. It was a fine place for the anopheles. When the Venetians had a plague they did not clean up or look to the material conditions, but they held processions, prayed to one of the saints, and when the plague died out they built a church in his honor. This, however, was not quite all. Eventually the city fathers got the idea that the fresh water was not a good thing to mix with the salt, and they finally turned aside the rivers emptying here, so that Venice now is surrounded and washed out twice a day with real and very salt sea water. There is now no malaria in Venice, although there are mosquitos. The city is supplied with excellent water from the mountains and the wells are mostly shut up, and there is no typhoid. The city is quite a healthy one (18 per 1,000 mortality annually); the people are lazy and look well-fed. They must have excellent eyes. I have not seen a Venetian child with glasses on, and here in the whole city there are only two opticians' shops. It is no place for an oculist, apparently, though who knows that its present decadence is not due to an unrecognized eye-strain, and that, if properly glassed, Venice would rise to some of its former glories? For Venice is not rising now. To be sure, she is rich and makes money, and her commerce is increasing, but this is all due to the Germans, who hold Northern Italy in the hollows of their hands. The Venetian is content to loaf about San Marco and talk gossip over his 5 cents worth of coffee. He has no originality in his art; his craftsmanship is that of blowing glass into silly shapes and blooming colors, in making the same, some lovely lace, and carving forever and ever the little stone angels, the winged lions, and cupids, and saints. There is no spirit of the renaissance here yet. He sings and jabbers all night; he works as little as he can, and always with a sort of sigh and a protest. He is a terrible drinker, but is not quarrelsome in his cups. Venice is said to have more alcoholism than any other city in Italy, yet in crimes of violence it ranks lowest (Vellari).

The drawbacks to Venice in summer are said to be these: the noise, the heat, and the mosquitos. A very fine polemic might be held over the question of noise. The Sixth avenue of New York during a working day has a greater output of noise than all Venice in a year. But the noises of Venice are in staccato; there are interruptions of relative silence. The church bells begin it at 5 o'clock A.M. or earlier, and from that time on they call to mass and strike the hours. At the same time the gondoliers begin to gibe and explain to each other across the canal and the "tongue-fights" beloved by Venetians pierce the ear. The penny steamers whistle, the morning cannon goes off, and so the day begins.

At night the music and talking and shouting and arguing continue into late hours. So that for practical purposes and to sensitive persons Venice may be called noisy at night. One, however, can get to like the bells and not to mind the screaming.

The heat of Venice is not so bad as that of New York, and is easily bearable if one keeps quiet in the midday and afternoon. The Lido is accessible in twenty minutes, and the bathing if not exciting at least cools one off. There is no surf, the water is shallow and warm, *i.e.* 22 degrees to 24 degrees C. The evenings are cool and life begins then to be enjoyable, even on the hottest days. The Venetian talks much of his sirocco, but it is only what we would call a cool sea breeze—a little humid. These are the experiences of perhaps an extra cool summer. The warm, soft air and outdoor life relax the nerves and help to sleep. Venice is a good place for the tired out person who wants rest and sleep—a delightful atmosphere and always something of interest to look upon.

Venice, if not a medical center, gets many important medical men as her guests. Visiting here recently was Dr. H. E. Plimmer, F.R.S., of London, who with Dr. Bateman has been studying experimentally the therapeutics of the "sleeping sickness." This disease has begun to attack the whites of Africa and will prove a serious menace to colonial development unless it can be controlled. Heretofore atoxyl has been the most efficient remedy, but Drs. Plimmer and Bateman, whose report was laid before the Royal Society in August, have had some remarkably encouraging results with antimony in the form of lithium antimonyl tartrate. This killed the trypanosomes in about one-half of the inoculated rats, and in all the inoculated dogs. Some trials of the metal (not yet formally reported) on human beings have been even more successful, the parasite in the blood having been apparently killed and a long remission, if not cure, effected. If antimony turns out to be so effective a therapeutic agent, we may have a return of the metal to favor. It had a tremendous vogue three hundred years ago.

The only original medical work produced in this city so far as I can learn is that of Mr. Horace Fletcher, the exponent of moderate eating and careful mastication. Mr. Fletcher has been lecturing in the United States in the last year, and his views are possibly known to medical men. He believes in a low proteid diet, and thinks that by masticating and insalivating the carbohydrates they are tolerated and support the system without poisoning it. I have seen several interesting cases in which as a result of "Fletcherizing" the sugars and cereals were digested and enjoyed, where before they were not borne at all. Mr. Fletcher's book, "The Art of Eating Little," has just been translated into Italian and has attracted much favorable criticism in the Italian press. Dr. Van Someren has carried out the method here under careful clinical conditions. There are certainly people whose metabolism responds to light, low proteid diet, and who are better and happier for it. How essential the mastication and insalivation, the use of the "food gate" and the stimulus of the food instinct are, may perhaps yet have to be worked out by further experiment. At any rate, it is an American who began working here in Venice at problems in diet and nutrition which have already led to certain practical results; even if the work succeeds only in ameliorating the prodigious proteid excess of the European *table d'hôte*, the traveler's life at least will be safer and more comfortable.

The Italian does not know what is meant by a hospital for the insane. There institutions are not hospitals in the native mind, but "manicomii," or madhouses. Venice has two—one for men and one for women—occupying small islands near the city. I visited the manicomio for men on San Servero. Dr. Perugia, the physician in charge, was at great pains to show me every detail of his establishment. The buildings, formerly a church and dormitory, occupy the whole island of several acres, they furnish many open courts and gardens for the patient, but no soil to cultivate and not much space for work or play. The wards were scrupulously clean, the attendants looked intelligent, but were all of the "orderly" type. The institution is apparently well supplied with money, and is very intelligently organized. There is a wonderful equipment of baths of every possible kind, including the continuous bath; there are a pathological and anthropological laboratory, a photographic outfit, and a system of history-taking, which seemed most admirable. A photograph of the patient goes with each record. The classification and grouping of patients is on most modern lines, except that the institution has to treat both acute and chronic cases on the same island. Altogether, Venice seems to take care of her insane in a more advanced way than of her sane sick. Perhaps it is because she has so many; I was told it was the craziest city in Italy. In the two asylums there is a population of about 1,200. Alcoholic forms of insanity are extremely frequent.

Crazy or not, the Venetians are a kindly people, and the city is progressing in wealth and material importance. It claims also artistic eminence, priority over Milan in music and over Munich in painting. I trust its medical interests will grow also; and I would not belittle what exists, for every resource is put at the service of the stranger. With an increase in the wealth and activity of the University of Padua, Venice ought to become, cooperating with its neighbor, a city of importance in learning and in the sciences.

Although Venice is lacking in opportunities for medical study and research, it is but just to say that in certain departments of medical art this city is far in advance of any in America. An enterprising company has installed here at the Lido an institute of mechanical therapeutics. It is under the patronage of the medical men of Venice, Bologna, and Padua, and it is equipped with every device known to our art for applying mechanics and chemistry to therapeutics. There is, first of all, a very complete Lander institute, occupying a large room by itself. Then in numerous adjoining rooms, all on the same floor, are apparatus for electric therapy, radiotherapy, magnetotherapy, vibrotherapy. In connection with this are hydriatric rooms in which are given every kind of baths, from the simple tub to the Wolf blue-light, carbonic acid, fango-mud, and the quadro electric. Among the more interesting things are the Leduc current and the monopolar current of Rumpf, of which Dr. Ravenna, in charge, spoke highly. There is the "cura Finsen" and an admirable apparatus for using the *x*-rays and a great variety of electric hot-air baths. Naturally, there are rooms for massage; there are rooms for inhalations, injections, suspensions, and the Frenkel reeducation therapy; blood and urine examinations are all made. The fees range from 2 to 5 francs. Two or three medical men are in charge. An inspection of this institute for kinetotherapy and a recollection of the resources of New York make one feel that ours is in some ways still a backward and provincial town. Perhaps for a time a little less money on our laboratories and more on our therapeutics would not be unwise.

CHARLES L. DANA.

VENICE, October 1, 1908.

OUR LONDON LETTER.

(From Our Special Correspondent.)

OPENING OF THE SCHOOLS—ADDRESS BY RUDYARD KIPLING—PLAGUE RESEARCH IN INDIA—REPORT ON MALARIA IN MAURITIUS—OBITUARY.

LONDON, October 2, 1908.

THE opening of the medical schools has been celebrated, yesterday and to-day, by dinners, conversazioni, and introductory addresses. At Charing Cross Hospital the occasion was commemorated by the delivery of the Huxley lecture by Sir Patrick Manson. At Kings College Professor Macalister gave a review of the progress of medical science during the last fifty years and of the effects of the theory of evolution. At St. Mary's Sir John Broadbent pointed out that, while advance in surgery meant a wider field for the surgeon, the reverse is the case with the work of the physician. At St. George's Dr. Slater dealt with the importance of the laboratory in modern medicine.

Mr. Rudyard Kipling distributed the prizes at the Middlesex Hospital and delighted his audience with a characteristic speech. He remarked that it might have escaped their professional observation that there were only two classes of mankind—doctors and patients. He

had felt a delicacy in confessing he belonged to the latter ever since a doctor told him that all patients were great liars where their own symptoms were concerned. The average patient might regard the doctor as the noncombatant does the troops who fought for him. He had to address the army which is always fighting against death. It was unfortunate that death was bound to win in the long run. This fight is one of the most important things in the world and you who carry it on, he said, must be among the most important people. The world certainly insists on this. It long ago decided you have no leisure that any one need respect. Nothing but extreme illness can excuse you in its eyes for refusing help to anyone who thinks he needs you at any hour of the day or night. Nobody will care whether you are in your bed or in your bath—at church or a theater. What vitality you have accumulated in your leisure will be dragged out of you again. In time of plague, pestilence, fire, battle, famine, murder, and sudden death it is required of you to go on your duty at once and stay till your strength fails or your conscience relieves you, whichever be the longer period. These are some of your obligations and not likely to grow lighter. Have you heard of any eight-hour bill for doctors? Do you know of any change in public opinion that will allow you to refuse to attend a patient who does not mean to pay? Have you heard any outcry against people who can well afford to pay but prefer to cadge around a free hospital and get advice, glass eyes, and cork legs for nothing? I have not. It is required of you to save others at all moments. It is nowhere laid down that you must save yourselves.

You have been and always will be exposed to the contempt of the gifted amateur, the gent who knows by intuition everything that has cost you years of study. You have also been and always will be exposed to the attacks of those persons who consider their own undisciplined emotions more important than the world's most bitter agonies—the people who would hamper and limit and cripple research because they fear that it may be accompanied by a little pain and suffering. Such people have been against you from the beginning, ever since the earliest Egyptians erected images in honor of cats and dogs on the banks of the Nile. But your work will go on. You remain perhaps the only class that dares tell the world that no man can get more out of a machine than he puts into it, and that if the fathers have eaten forbidden fruit the children's teeth will be set on edge. In a day when few things are called by their right names you are joining a profession in which it pays to tell the truth. Realizing these things, I need not task your patience by talking about the high ideals and lofty ethics of that profession—so I will wish you enough work to do and strength to do the work.

Why disinfectants have proved of so little value against the spread of plague has been a cause of anxiety to sanitarians. It would appear that some of the reasons have at length been satisfactorily demonstrated. The Plague Research Commission found that rooms retained their infection after most thorough treatment with mercury perchloride. Light is thrown on the reason of resistance to this agent by a report of Captain Liston, I.M.S., of the Bombay Bacteriological Laboratory, which records the results of a research by Captain T. H. Gloster, I.M.S. Aerial infection may be put on one side as a cause of epidemics, and so may the excreta, since if they contain bacilli these are rapidly destroyed in India. This destruction may be brought about by disinfection, but even in a moist state the excrete are speedily dealt with by the saprophytic bacteria, which rapidly develop and multiply in such conditions. It is the rat, or rather the rat's flea, with which we have to contend. In the body of this flea the plague bacilli are inaccessible to the natural disinfectants. In the insect's stomach they find their food—the blood of its host. On the death of the flea they perish by desiccation or from the saprophytic bacteria. The flea sucks the infection from a rat attacked by plague. To stamp out plague, therefore, we need to destroy all infected rats and their fleas. But the habits of rats render it very difficult to exterminate them. A gaseous disinfectant would seem to promise success, provided it could be forced into the secret lairs of the rats. Attempts have been begun in this direction. Meantime the study of liquid disinfectants has not been neglected. The Plague Research Commission showed that rooms cannot be successfully disinfected by mercury perchloride—1 in 750. But Captain Gloster's experiments prove that an emulsion of kerosene oil is an effective disinfectant against plague. Rooms which were infected and in which a succession of guinea-pigs put there for the experiment all died were afterwards thoroughly washed with the emulsion, and guinea-pigs put there after this washing lived. Accordingly Captain Liston strongly recommends kerosene oil emulsion as an easy method of disinfection. The emulsion is made with 3 parts of soap dissolved in 15 of boiling water. To this solution the kerosene oil, gently warmed, is added, gradually up to 100 parts, shaking and stirring well. Kerosene seems to be remarkably pernicious to fleas, for it kills them in as weak a dilution as 1 in 1,000, while they seem to be indifferent to a bath of mercury perchloride.

Professor Ronald Ross has presented to the Colonial Office his report on malaria in Mauritius, which colony he visited at the desire of the Colonial Secretary. His observations and recommendations are as clearly put as usual, and his report is likely to be useful in tropical countries. People who can avoid it are advised not to live in malarious districts, and when they cannot recognized precautions should not be neglected. Mosquito nets must be regularly used and the smallest hole at once be repaired. It is especially advisable to protect a room or a veranda for use during the day or evening. Punkas and fans not only drive away insects, but keep the body cool. Where there is great danger he recommends quinine to be taken, 5 grains before breakfast daily and a double dose on Sundays.

In dealing with public prevention Dr. Ross remarks that as a broad general rule malaria causes from one-fourth to one-half the total sickness in the tropics. It can always be reduced or even extirpated. Large marshes must be drained, deepened, or filled up. A permanent organization must be established for dealing with the breeding places of anopheles and for distributing quinine, especially to infected children. Such a campaign would get rid of other diseases as well as malaria and improve any tropical locality. The heavy losses of the colony caused by malaria are pointed out on the estimate of Dr. Bolton. In these are included not only the sickness and death, but the loss of labor, wages, etc.

Professor R. Ross outlines a "general plan of campaign," which, he says, should not be confined to a few localities, but be extended to all the populous parts of the colony, and the cost would not be very great. Minor campaigns, he thinks, fritter away considerable sums without producing a marked effect on the total amount of sickness. This campaign should be begun simultaneously and vigorously throughout the land, before the beginning of the malaria season. The chief object is to deliver as heavy a blow as possible upon the disease at the commencement of the malaria season, in the assurance that every case cured and every infection thereby prevented will save many more infections later on. He recommends periodical examination of children in the schools, as well as on the estates, and the continuous treatment of all those who may be found suffering from enlarged spleen; continuous house-to-house distribution of quinine, where necessary, and treatment of fever patients on the estates; continuous performance of minor works where required, in towns, villages, and indeed all populous areas, by malarial gangs engaged for the purpose; similar efforts on the estates; and further the appointment of a malarial authority for the island.

By the death of Sir Arthur Macan, which took place on Sunday, Ireland loses one of her most distinguished members of the profession. He was president of the Royal College of Physicians in 1904, was ex-master of the Rotunda Hospital, King's professor of midwifery, T.C.D. and gynecologist to Sir Patrick Dun's Hospital. He was a Dublin graduate in arts and medicine, 1868, became F.R.C.P., 1877. He has been president of the Gynecological Society, of the Obstetric Section of the International Congress at Berlin, and held many other posts of renown. He translated Heller's article on "Intestinal Parasites" for Ziemssen's Cyclopedia, and contributed various articles to the journals on obstetrical and gynecological subjects, chiefly to the *Dublin Medical Journal.*

Diet of Nursing Women.—L. Bouchacourt regulates the diet of nursing women in such a way as to produce the most milk and of the best quality. The diet must be abundant and of good quality, but vegetable matters should predominate, meats being less important as milk formers. Oils are also valuable. The vegetables that give the best results are lentils, peas, beans, beets, chicory, parsley, cottonseed oil cakes, and carrots. Cod-liver oil is also valuable. Plenty of milk, butter, and cheese should be given daily. Plenty of liquids are also important, and the author believes that light beers, ales, and cider have galactogogue properties.—*Journal de Médecine de Paris.*

Progress of Medical Science.

Boston Medicol and Surgical Journal, October 8, 1908.

The Relation of Carcinoma of the Corpus Uteri to Fibroids.—The conclusions of J. T. Williams are as follows: (1) There is a distinct relationship between carcinoma of the corpus uteri and fibromyomata. (2) This relationship probably lies in certain common etiological conditions. (3) The predisposition of fibroids to become complicated with cancer does not constitute an indication for their routine removal as soon as discovered, providing the patient can be kept under close observation. (4) Any marked increase in the loss of blood from a fibroid, or the appearance of any vaginal discharge in the intervals between the hemorrhages should be regarded as suggestive of the development of carcinoma. (5) In a fibroid where either of these symptoms is present an immediate curettage should be performed in order that the condition of the endometrium may be examined, even if a radical operation has been decided upon. (6) Every uterus removed for fibroids should be immediately opened by an assistant and the endometrium inspected to guard against possible oversight of a malignant process. (7) In all cases of fibroids complicated by adenocarcinoma of the corpus a complete removal of the uterus including the cervix is the operation of choice.

Tumors of Adrenal Origin with Particular Reference to Hypernephroma of the Kidney.—After some reference to the anatomy and physiology of the adrenal bodies, H. C. Moffitt reports nine cases, adding a full bibliography of the subject. It is extremely difficult to make any clinical distinction between such growths and renal hypernephroma. Some of the most important diagnostic points in the latter condition are thus given: (1) Hematuria, a common symptom and often the first. Its exact character and origin must be determined by cystoscopy. (2) Pain is an early symptom and may for a long time preclude any other manifestation. It may vary much in character and exact location. (3) The tumor varies greatly in size and in rapidity of growth. It may be present for years without giving trouble and may suddenly assume a malignant character. In addition to the pain it causes, it frequently produces pressure symptoms. Varicocele is often present, usually on the left side. Its peculiarities are appearance late in life, usually without pain, rapid onset, persistence when the patient lies down, but disappearance when the patient is put in the knee-chest position so as to remove pressure of the tumor from the veins. (4) Metastases frequently occur in the lungs, liver, and bones. Pulsating bone tumors should always arouse suspicion of metastases from either adrenals or thyroids. (5) Pigmentation has been observed in only a few cases. (6) Trophic changes are often in evidence in the shape of abnormal genital development or general overgrowth in childhood. (7) The urine may remain normal for years, in spite of the presence of a renal tumor. Polyuria is not uncommon. Albuminuria may be present. (8) *X*-ray plates are of great value in differentiating hematuria due to stone, although it must be remembered that stone and tumor may coexist and that calcification in a tumor may simulate stone. Results of operation for this class of growths have thus far been disheartening.

New York Medical Journal, October 10, 1908.

Conservatism in Surgery of the Hands.—A plea for conservatism in all surgical procedures on the hand is made by J. A. Hofheimer, who notes that beginners are apt to overdo matters, particularly if the case is not seen until several days after the injury, by which time cellulitis or lymphangitis may have occurred. A series of six cases is reported, illustrating the benefits of conservative measures. Healing may require longer under these circumstances than when amputations are done, but the results more than justify the delay. The author says that very often the ambition or necessity of the patient compel him to resume work early, and he is not willing to submit to a prolonged period of invalidism, but the surgeon's duty is not to be limited by the patient's desire. After an injury the crushing, bruising, or frequent infection causes a temporary destruction of the parts; these have to be cut off and a healthy growth encouraged. In amputation the tissues to be operated on can be selected and primary union obtained. This advantage often leads to errors of judgment, but immediate brilliant results are not to be compared with the advantages of more remote preservation of function. When there is the slightest chance of saving a part of the human economy, endeavor should be made in that direction. Utility of a member is important to a wage earner, but a small part of a finger is better than none at all.

The Stomach and Intestinal Gases.—An elaborate tabulated paper on this subject is presented by S. Basch, who describes an apparatus for the collection and analysis of these gases. In a general way they were aspirated into a pear-shaped bottle. In the stomach we find (1) oxygen and nitrogen from air swallowed with or independently of, food and drink. (2) Nitrogen, carbonic acid gas, sulphuretted hydrogen, ammonia, and other gases contained in food, drink, medicated liquids, and mineral waters, and (3) gases originating within the stomach itself, from fermentative processes, such as carbon dioxide, hydrogen, and ammonia. The author gives his results with analyses of the gases taken from the stomachs of three patients who were suffering from, respectively, cancer, benign stenosis of the pylorus, and a perigastric abscess communicating with the stomach. Gases in the intestine (1) may enter from the stomach, (2) nitrogen and carbon dioxide may diffuse in from the blood, but (3) most of them are formed in the bowel through fermentation, bacterial decomposition, and in the upper bowel through chemical composition of the alkaline carbonates of the intestinal secretions by the acid chyme and fatty acids. Almost none are formed in the large bowel except in cases of hyperperistalsis without obstruction. Here the contents are rushed through so rapidly that gas formation is practically uniform throughout the entire bowel. Carbohydrates yield hydrogen, carbon dioxide, and other hydrocarbons. Proteids yield less carbonic acid gas, but in addition, hydrogen, marsh gas, nitrogen, ammonia, and sulphuretted hydrogen. Much of the gas does not pass out through the anus, but is diffused into the blood and leaves the body through the lungs.

The Mechanicobiological Standpoint in Medical Problems.—A series of papers on this general topic is introduced by J. Wright with a contribution on the physical processes in immunity and infection, the writer referring freely to his own previous writings and those of others on this and kindred topics. It has been shown that dust, saponified oil globules, and bacteria (under certain conditions) pass through the epithelium of both the tonsils and intestines. This probably arises from the difference between the potentials of surface tension of the epithelial cell on the one hand and that of the dust or bacteria on the other. One kind of matter is harmless, and the other often harmful. Evolution has consequently stepped in by natural selection or otherwise. The author reviews recent literature in the field of investigation. In general it would appear that the action of one body upon another at a distance through the medium of bodily or other currents bears a striking analogy to those interactions of one electrified body upon another at a distance through the medium of electric currents in the ether. The difference in the terms of the equations and in the results of their functions seem solely due to the differences in the physical properties for water or other real fluids and those of ether as theoretically formulated by physical science. The "pulsating molecule of life," a struggle with syntax to subordinate complex phenomena to our finite comprehension, the radiation of lines of force from the centrosome and the various phenomena here referred to, by those attempts at correlation assume a significant influence. It seems apparent, then, that to the changes constantly wrought in fluid protoplasm we must apply not only the laws of electrodynamics, but the laws of hydrodynamics. Variations in these laws, or rather variations in the conditions under which they manifest themselves, probably explain why *e.g.*, it comes about that various bacteria constantly found on tonsillar and other surfaces are at times harmless and again harmful. The author notes that in watching under the microscope for evidence that such bodies as carmine granules enter the epithelial cells in their path to the deeper lymph channels he was unable to see that they did so. In fact phagocytoses during quiescent conditions of the tonsil did not seem to take place in the superficial regions of the tonsil. It would seem that the forces which take the granules beneath the surface are those with which we are familiar under the name of capillary attraction, but the author regards the question as more complex than this.

Journal of the American Medical Association, October 10, 1908.

Idiopathic Multiple Hemorrhagic Sarcoma.—Dr. Lieberthal reports a case in detail, including microscopic examination of the excised morbid tissue. Very few cases of this disease have been reported from this country, and most of them in patients of foreign birth. The patient in the present case was a native American. The disease begins on the hands and feet in the form of reddish brown or bluish red, rather firm, soft or spongy nodules, nodes or plaques or diffuse swellings. By the development of dis-

crete formations it advances along the legs and arms and gradually reaches the trunk, face, and mucous membranes. Some of the lesions may atrophy, wholly or in part, leaving pigmented depressions. Ulceration is rare, but the lesions, especially on the limbs, are generally painful. Horny growths have been developed in a number of cases. Usually the subcutaneous structures escape, but they have been found involved in some cases. Microscopic examination shows numerous cavities in the corium lined with endothelium and, between these, accumulations of small spindle cells in bundle or streak-like formation or in irregular masses. The sarcomatous nature of the disorder, held by Kaposi has been questioned, largely on account of the possible spontaneous involution of the lesions. Lieberthal refers, as regards this point, to the memoir of Fano, in which the views of various high authorities are given, which to a certain degree mitigate the sharp differences between sarcoma proper and idopathic, multiple hemorrhagic sarcoma. The cause of the disorder is unknown.

Nasal Duct Strictures.—H. Moulton advocates the use of lead styles in the treatment of nasal duct strictures, especially such as are resistant to other methods of treatment. The advantages of the material are, that it is cheap, easily obtained, pliable, and readily shaped by the surgeon; comfortable to the patient, and not acted on by the secretions as are aluminum and silver in the course of time. He finds the fuse wire used by electricians the best adapted for this purpose. It contains a little antimony, which is rather an advantage than otherwise; can be obtained in different sizes, the best being those of 1, 1.5, and 2 mm. diameter; or the wire can be compared directly with the lacrymal probe. He gives directions as to the fitting and insertion of the style which are important, care being needed that it fits the canal without causing tension. After the first few hours the patient is unconscious of its presence and the secretions readily find their way down along its side. It is well to remove the style every three or four weeks and see that all is well, but he has frequently allowed it to remain a month or longer, and in one case it remained over six months with good result. As a rule, after a style has been worn a month or two, he takes it out for a week. Then, if syringing is at all difficult, he reinserts it for another month. The very old cases of tight stricture require the longer time for a cure. In no case is appropriate nasal or other treatment that may be required to be neglected. In his hands this treatment has been so uniformly successful that he hopes it will be more generally tried by other ophthalmologists. He does not claim to be the originator of the method, or advise it as a universal one, but thinks that it will be found effective in a large proportion of obstinate cases.

Breast Milk Feeding.—Effa V. Davis, from a careful study of 100 cases in the first two weeks of the puerperium in hospital practice, including observation and regulation of the mother's diet, regular weighings of infants and analysis of breast milk, comes to substantially the following conclusions: 1. The system of estimating the quantity of breast milk by weight is a decided aid in making a feeding schedule for the newborn infant. 2. Both mother and child must be considered in deducing any thoroughly useful rules. 3. The early secretion from the mother's breast is useful in sustaining the child, and infants should be encouraged to nurse from the first day of life, whenever possible. 4. When the milk is abundant, a three-hour interval soon becomes the shortest for feeding in the daytime, but a longer interval at night can be borne by the child with benefit. 5. Both the digestive capacity of the child and the quantity of breast milk may affect the results, without regard to the times and quantity of feeding.

Rat Leprosy.—Fourteen cases of rat leprosy were found by Agnes Walker in the examination of 2,780 rats, all of the common Norway species. The pathological condition was much as observed by others, thickening of the skin, nodules in one case only, but ulcers in nearly every case containing enormous numbers of the acid-fast bacilli, morphologically identical with those of human leprosy. The granules observed by McCoy and the subcutaneous congestion noted by Wherry were not noticed. The question as to the relationship between this disease of rats and human leprosy can not at present be answered, but the comparative frequency in rats and rarity in the human species in that locality suggests, she thinks, that it may not be transmissible to man from rats or that the contact is not sufficiently intimate to favor the transmission.

Heredity and Insanity.—E. Cohn says that hereditary tendencies are very manifest in insanity, and he thinks if we could get the exact facts in all cases the high estimate of 90 per cent. of cases attributable to hereditary causes would probably be found not far from the truth. Even in cases of apparently purely acquired insanity some hereditary defect or predisposition may have made the patient an easier victim. Intermarriage, alcoholism of parents, drug habits, etc., are cited as effective factors in the production of mental disease. It is unfortunate, he thinks, that we can not have federal laws preventing the crowding together of immigrants in great centers where they concentrate and propagate their hereditary defects. The remedy for the conditions he sees in better methods of education, the teaching of right ideals in our public schools, instruction of the public in regard to the transmission of hereditary defects, and higher and better standards of morality.

The Lancet, September 26 and October 3, 1908.

The Therapeutic Value of Stock Vaccines in the Treatment of Bacterial Infections.—The general principles underlying the mode of therapy are described by J. Williams, who defines a "vaccine" as a killed bacterial culture suspended in normal saline to which ¼ per cent. lysol, or ½ per cent. carbolic acid has been added. Their injection into healthy individuals causes (1) an immediate rise in the protective substances as indicated by the opsonic index, (2) a fall of longer or shorter duration, followed by a rise up to or above normal, with a succeeding fall to normal and (3) a fall tending to be more or less permanent, according to small, medium or excessive dosage. The intelligent use of vaccines presupposes (1) diagnosis of the bacterium at fault, isolation and culture and preparation of a vaccine, and (2) the estimation of the amount which for a given case constitutes a proper dose and the correct determination of the period which should elapse before inoculation. These points are elaborated in considerable detail. In the institution with which the author is connected it has been found practicable to dispense tubercle (T.R.), staphylococcus, streptococcus, gonococcus and typhoid vaccines. Experiments seem to promise the addition of a vaccine of micrococcus performance for its beneficial results in lessening pain and retarding growth, and secondary deposits in some forms of cancer. The paper of Dr. Williams will serve as a valuable introduction to anyone wishing to take up the study of vaccine therapy.

Vaccine Therapy in General Practice.—The paper of L. Grant, T. H. Campbell and W. D. Anderson is a record of personal experience with four cases. Two were tuberculous, one presented staphylococcus infection, and one, encapsulated pneumococci mixed with Friedlander's pneumococci. In the tuberculous cases, T.R. tubuculin was used, and in the other two the proper vaccine prepared *secundum artem*. Results were satisfactory in all four cases. In the cases treated with tuberculin the following facts are emphasized: (1) The scars resulting were soft, pliable and the disfigurement (following certain operative procedures) slight. (2) Recovery under the treatment seemed rapid, and this implied saving of suffering and expense to the patient and anxiety to the medical attendants. (3) The absence of severe surgical measures minimized the risk of a general tuberculous infection and obviated that slight risk which always attends general anesthesia. (4) Although opsonic estimations were only made occasionally during the treatment, they suggested that the index was being steadily raised, and from this it is probable that for some time, at least, the patients will be less susceptible to attacks by the same bacterium. Surgical measures alone may achieve this indirectly, inasmuch as they rid the body of the focus of the disease, but it is questionable if they are capable of raising the standard of defense to the same high level as that induced by vaccine therapy.

Diffuse Painful Lipoma of the Foot.—The first patient of A. H. Tubby was a hospital nurse, woman, aged 25 years, who three months before coming under observation had complained of pain in the feet. Examination showed an oval swelling on each foot on the inner side and just below the sustentaculum tali, encroaching on the weight-bearing surface of the feet and measuring almost one by one and a half inches. A diagnosis of lipoma was made and confirmed by operation. Recovery was uneventful. The growth was highly vascular and bled considerably. The second case was that of a girl of 16 years with a swelling on the inner side of the right foot, semicystic in character and almost one inch in diameter. Operation showed the same fatty and vascular condition as in the previous case. The author notes certain differences in such growths as compared with congenital diffuse lipoma. In the latter the main part of the microscopic section is occupied by fat and areolar tissue, yet the interfibrous spaces are occupied, are crowded by small round cells, not unlike those seen in round-celled sarcoma, and clinically the diffuse congenital form of lipoma is somewhat akin to sarcoma, in that it shows an inveterate tendency to recur very rapidly after removal. In the acquired diffuse form, such as reported in this paper, no such appearances are evident,

but the bloodvessels are extremely numerous and somewhat hypertrophied. With reference to the clinical features of these acquired cases, the author notes that on careful observation the swellings due to acquired painful diffuse lipoma may partially fill up the arches of the feet, so that the condition can be mistaken for flat foot; but in all the cases the author has seen, numbering now five, the tumors have always been between the inner edge of the sole of the foot and the internal malleolus, and have not extended further forward than the anterior part of the sustentaculum tali. In no case has he seen them over the scaphoid or internal cuneiform bone. The striking features about them are their slow growth and their indolence, their extreme tenderness, and their vascularity when cut into. It is also noticeable that any pressure, whether arising from an irregularity on the inside of the boot or from the employment of a "flatfoot" pad, renders the patient completely unable to get about on account of the pain. Finally, on removal, they do not, as far as is known, recur, and in this respect are entirely different from the congenital diffuse lipoma.

Rheumatic Hyperpyrexia.—In a patient of T. E. Meyber, a boy of nine years with a seven weeks' history of stiff neck and slight leg pains, examination revealed a presystolic initial murmur with a flaccid and paralyzed arm. The condition went along for four days without change when the boy suddenly developed stertorous breathing and became comatose. The temperature was 109° and the pulse uncountable. The patient died in an hour with a temperature of 110°. The author notes the variety of hyperpyrexia during acute rheumatism in children, and its greater frequency in first attacks and in those which run a mild course.

Treatment of Inoperable Cancer.—Henry Morris regards cancer as at first a local affection, and would divide inoperable cases into four groups: (1) Primary cancer affecting inaccessible parts and organs; (2) primary cancer which though originating in an accessible part or organ of the body has been allowed to extend beyond the limits within which an operation is prudent and complete removal possible; (3) certain cases of acute diffuse carcinoma and very rapidly growing or widely infiltrating new growths of exceptionally virulent character; and (4) recurrent cancer, where the disease has recurred in multiple metastatic foci or in parts beyond the limits of removal. Many of the cases included in these groups are submitted to operation for the purpose of palliating symptoms or prolonging life. Hence the term "treatment" as applied to inoperable cancer means one of two things: (1) The employment of remedies and methods other than the knife, to cure, ameliorate, or retard the disease, as well as to prevent relapses after its removal; or (2) the employment of the knife to give relief from pain, to prolong life, to restore function, and otherwise to make the patient's condition more tolerable. The remainder of the paper is an application of the principle of therapy above enumerated to cancers in various bodily areas. The various operatic measures and cauterizing agents are passed in review. Concerning trypsin solution, the author writes very cautiously, and believes it has yet to justify its use. He declares that Beard's results have not yet been duplicated by any other observer. The paper gives a very candid review of the present status of the pancreatic ferment therapy.

British Medical Journal, October 3, 1908.

Family Pneumonia.—G. Norman notes the susceptibility and want of resistance power in some families as regards pneumonia, and reports a series of seven cases with five deaths in the same family. Three generations lived in one house. The first case was that of the grandmother, who died on the sixth day of the disease (apex lesions) after a prodroma of grippe; second, her daughter-in-law, who had been attacked with fever and diarrhea at the same time, died three days later with a middle lobe pneumonia. A child and a niece of the second patient living in an adjoining house developed the disease on the day after the mother's and aunt's death, but both recovered (apex lesions). One week later the grandfather was stricken (apex), and died on the third day. Sixteen days later another child (cousin to the preceding) developed measles with complicating pneumonia and died in two weeks. About a month after, the seventh case, an infant three months old, came down with a gastric disturbance, but after a temporary improvement developed pneumonia (base) and died on the fifth day from the onset of symptoms, and ten hours after the diagnosis of pneumonia was possible. Nothing could be detected as regards unsanitary conditions in either dwelling. During the same season there were other cases of the disease in the same general locality, but with few fatalities.

Oxygen and Muscular Exercise as a Form of Treatment.—This therapy is commended by L. Hill, who says that he has noted its good effects on swimmers, athletes, work horses, and trotting horses. He has constructed (and describes) a small portable apparatus which is in effect a combined generator and inhaler. He has no doubt that oxygen in connection with exercise has a most beneficial effect on untrained or fatigued men. It enables them to increase greatly the bodily metabolism. It should be of value, therefore, in the treatment of people who are fat and scant of breath, and those who overeat and take too little exercise, and in cases of emphysema and of heart disease treated by graduated exercise. It may find a use in tropical regions to make exercise easier and in men who are exhausted by a day's mental work and worry. The author's paper is followed by a report of Mr. Flack on the case of Wolffe, the man who tried to swim the English Channel and to whom oxygen was administered while he was in the water. The swimmer gave out when only a quarter of a mile from the end of his route, and while the oxygen did not stave off fatigue, it demonstrated its great value in relieving fatigue of a most advanced type.

Münchener medizinische Wochenschrift, September 22, 1908.

Dietetic Causes of Nervousness in Children.—Siegert says that in addition to the hereditary nervousness of children there is another form which is proved to be acquired by the rapid convalescence and cure of the patients under proper management. The most important cause of the latter type of nervous disturbance is found in improper diet, especially the co-called "nourishing" diet, which is often prescribed for children. Usually there is an overabundance of proteid in such a diet, while fat is also well represented; vegetables and fruits are frequently not given because of their supposedly small nutritive value. Restlessness, lack of attention in school, constipation, anemia, skin affections, night terrors and insomnia are often caused by this disproportion between the requirements of the organism in proteid and fat and the quantities of them consumed by the child. No medicinal treatment proves of any use, but simple change in the diet with increase of vegetables and fruit running parallel with gradual but decided reduction of proteid and fat soon leads to amelioration of the symptoms and finally to complete restitution of the patient to health. The treatment, then, is very simple, but the diagnosis is made difficult by the widespread idea of the inherited character of most nervousness in children. Complete history with details as to the amount and kind of food given is the best aid in arriving at the correct interpretation of the condition present in these cases. The treatment, too, while simple, must be faithfully adhered to for long periods of time in order to save the child from reaching maturity handicapped by a badly balanced nervous system.

Removal of Tonsils.—Hopmann says that the usual objections to removing tonsils, such as the uselessness of the operation, the harm done by removing protective lymphatic systems at the portals of entry for possible infections, the great danger of narcosis in children, etc., are answered not so much by theoretical considerations as by the practical results obtained. Partial operations, on the other hand, may be properly objected to the mutilated lymphatic organ left on their performance being as much a source of danger as the hypertrophied organ before the operation. The great danger of the hypertrophied and diseased tonsils or adenoids consists in the favorable culture ground which they furnish to various bacteria that reach them from the constantly infected mouth and pharynx; thus of 300 tonsils examined, 43 per cent. were found to contain infected areas or foci of putrefaction. The earlier the operation is performed the less chance is there of general infections with such chronic disease as tuberculosis. General narcosis must be insisted upon in all cases, for it is only in its use that the opportunity is given for a complete and careful removal of the tonsillar and adenoid tissue.

Congenital Syphilis and Progressive Paralysis.—Müller says that Wassermann's researches have finally proved that without syphilis there can be no progressive paralysis. The fact that some 10 per cent. of paralytics do not give any history of syphilis is explained by the possibility of ignorance of the existence of the disease, which is often the case in women, and the well-recognized untrustworthiness of all venereal patients. Still more important is the fact that paralysis may occur in consequence of inherited syphilis. Müller reports three cases of progressive paralysis in such patients. That they are more frequent than is usually thought is probable, when the extraordinary distribution of syphilitic infection in all classes of people is considered. Often, therefore, a careful family history and an examination of the patient's parents may clear the mystery of a progressive paralysis in apparent absence of any leutic infection.

Book Reviews.

Protozoa and Disease, Comprising Sections on the Causation of Smallpox, Syphilis, and Cancer. By J. Jackson Clarke, M.B. (Lond.), F.R.C.S. Part II. New York: Wm. Wood & Co., 1908.

This is a thoroughly comprehensive and up-to-date résumé of the life history of those protozoa which are responsible for disease in the human organism. The author is not an extremist, yet he believes that we have already established beyond doubt that yellow fever, tick fever, smallpox, hydrophobia, molluscum contagiosum, trachoma, syphilis, carcinoma and sarcoma are of protozoic origin. He declares that it has been well established for five years that certain hyaline bodies appearing in the corneal cells of rodents, when inoculated with variolous matter may be relied on to make the diagnosis of smallpox. Moreover, the Negri corpuscles can be made out by simply pressing a cover glass upon the *cornu ammonis* staining and examining. Their presence he regards as proof positive of hydrophobia, and thus priceless time may be saved to a supposedly infected patient. The author uses the term "cancer" to include all common forms of malignant disease whether of the epithelial or connective tissue type. He goes back to the cell theory of Schleiden and Schwann enunciated in 1838 and upholds Virchow's belief that constituent cells of cancer are lineal descendants of cells formerly an integral part of the body in which the tumor grew. As an evidence of the great progress that has been made during the past decade in the interpretation of protozoa as factors in disease, this book is the most illuminating we have yet seen.

Grundriss der Allgemeinen Symptomatologie. Für Aerzte und Studierende von Dr. med. R. Oestreich, Privatdozent für Allgemeine Pathologie und pathologische Anatomie; Prosektor des Königen Augusta Hospitals in Berlin. Berlin: August Hirschwald, 1908.

This work is based on an extensive postmortem experience and is written with the intention of fixing in the clinician's mind the pathological conditions which may be associated with various subjective and objective symptoms. After some general observations on symptoms and their relation to disease the author takes up various objective symptoms describing clearly how any one of them may be caused by various diseases of the internal organs. He discusses the numerous varieties of each objective symptom, such as the different kinds of dyspnea, pulse, etc., showing how one variety may suggest more strongly one disease than another. In the latter half of the book the writer briefly describes the symptomatology of the various diseases of the internal organs, laying special stress on differential diagnosis. The book is to be recommended to both the student and general practitioner, because it very clearly and concisely indicates how to interpret objective symptoms in order to arrive at a correct diagnosis.

Vitality, Fasting and Nutrition. A Physiological Study of the Curative Power of Fasting, Together with a New Theory of the Relation of Food to Human Vitality. By Hereward Carrington. With an Introduction by A. Rabagliati, M.A., M.D., F.R.C.S. New York: The Rebman Co., 1908.

This is a remarkable book and one that will probably call down upon the author's head the wrath and contumely of the unbeliever. He seems to have gone to work with a purpose of setting us all by the ears, and turning topsyturvy pretty much every conceivable notion of present-day physiology. But if we disagree with him on many of the issues he raises, he sets us thinking by the very audacity of his concepts, and the ingenious way in which he postulates what most scientific men will consider impossibilities. His theory of fasting as a cure for human ills did not originate with him, but with a certain Dr. Dewey; so we are told. In the following up of Dewey's theories, Mr. Carrington has succeeded in filling more than 600 pages with statement, argument, and exhortation, to-wit: that food does not give strength or energy, but on the contrary detracts from both; that mankind would live longer and be happier if it followed the "no-breakfast" plan; that food supplies new tissue only and does not supply energy or vital force; that vitality cannot be made but must flow into us somewhat as does the soul at birth, and that the purpose of sleep is a renewal of vital force. This is by no means all, but it perhaps is enough to begin with.

Urogenital Therapeutics, Medical and Surgical. A Treatise on the Practical Treatment of Diseases of the Urinary and Genital System, by Fillip Kreissl, M.D. Chicago: The Cleveland Press, 1908.

This work, as its title indicates, deals only with the treatment of genitourinary diseases. The author in his introductory assumes in the reader "a knowledge of the physiology and pathology of the urogenital tract and familiarity with the recognized methods of diagnosis in this tract * * *" From this viewpoint the work certainly justifies its existence. It must be conceded that the majority of practitioners are more interested in the treatment of disease than in recondite pathological research. To the majority, therefore, the book will prove extremely acceptable. The specialist, too, obliged to give general practitioners at least a synopsis of the treatment of their cases, will find it very convenient to refer them to Kreissl's book. The tone of the work is somewhat magisterial; but the author certainly embraces within a relatively small volume for so large a subject, all the methods of treatment. That he mentions some which are still in the experimental stage, as, for instance, the serum treatment of systemic gonorrhea, is doubtless for the sake of completeness. Covering, as this book does, the entire medical and surgical therapeutics of diseases of the genitourinary apparatus, and those of syphilis and sexual derangements as well, the author presents his subject admirably. The value of the book for rapid reference would be materially enhanced, if future editions were provided with a more exhaustive index. The 149 illustrations, many of them original, materially assist in comprehension of the text. The mechanical part of the work does credit to the publishers.

Outlines of Physiology. By Edward Groves Jones, A.B., M.D., Professor of Surgery in Atlanta School of Medicine, and Robert Grier Stephen, A.B., M.D., Instructor in Physiology in the Atlanta School of Medicine. Second Edition, Revised; 107 Illustrations. Philadelphia: P. Blakiston's Son & Co., 1908.

Dr. Stephens has revised the little book of Dr. Jones and has rearranged the subject matter. The introduction, containing definitions and scope of the divisions of physiology, has been entirely rewritten; the chapters on circulation and on the chemical constituents of the body are likewise recast. A new chapter on the "Blood" has been inserted as an introduction to the consideration of circulation. The book retains its character as a handy *résumé* of the subject which ought to prove useful to the student reviewing the subject and to the busy physician who wants to brush up his knowledge of physiology. It cannot, of course, take the place of the larger works as a college textbook. In its special field, however, it is one of the best books of "Outlines" that we have seen.

Le Cancer. Prophylaxie, Etiologie, Traitement. Par le Docteur C. Sobre-Casas (Buenos-Aires). Paris: G. Steinheil, 1908.

While Dr. Sobre-Casas has put very little of his own views into this book, nevertheless he deserves the thanks and praise of everyone who is fortunate enough to be able to peruse it. As a compilation of the best that has been said and written on the great cancer problem this little volume is a model for all that shall come after. So far as one can determine, the author has not missed a single important point, and this is by no means extravagant praise.

The first chapter considers the prophylaxis and defense against cancer, followed by a review of its actual status in Germany, England, France, the United States, Austria-Hungary, Russia, Spain, Portugal, Italy, and the Argentine. The parasitic and nonparasitic theories of origin are thoroughly reviewed and discussed, while contributory and predisposing causes receive due attention. Chapter IV. is devoted to the various kinds of treatment which have been tried, and an attempt is made to determine the true worth of each. There is a chapter on general hygiene and a brief one on our present knowledge of the cancerous maladies. Eight full pages are given to bibliography. We believe that this essay will prove indispensable to all students of malignant disease.

Practical Life Insurance Examinations. With a Chapter on the Insurance of Sub-standard Lives. By Murray Elliott Ramsey, M.D. Philadelphia: J, B. Lippincott Co., 1908.

After many years' experience as an examiner for life insurance companies, Dr. Ramsey has prepared this book, with the single purpose of placing before the examiner what will be expected of him in the way of interpreting such facts as may be revealed by the examination. The volume is essentially a compendium on physical diagnosis with such references to prognosis as are essential in determining the validity of a "risk." Especial attention has been directed to diseases of the chest and abdomen, and the chapter on sub-standard insurance is in this respect well done. The author approaches his subject with a due sense of the obligations resting upon the examiner, and he warns against careless work as a violation of trust reposed in the latter by both the public and the company. The volume is carefully written, and will prove a helpful one to the specialist in this branch of medicine.

Society Reports.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Thirty-sixth Annual Meeting, Held at Winnipeg, Manitoba, August 25, 26, 27 and 28, 1908.

THE PRESIDENT, DR. RICHARD H. LEWIS, OF RALEIGH, N. C., IN THE CHAIR.

Report of Committee on Ophthalmia Neonatorum.—Dr. F. PARK LEWIS of Buffalo, N. Y., Chairman, presented a lengthy report on this subject, in which he stated that ophthalmia neonatorum was still a most prominent cause of much unnecessary blindness. The efforts that had been made had already lessened its disastrous results in a large degree, but in many instances where it seemed to be infrequent it would be found to be producing blindness among the poorest and most neglected classes. In these the burden on the public treasury was greater because the victims of this neglect became almost inevitably charges upon the State. The responsibility for the investigation, the recognition, and the control of this infection rested upon the Department of Public Health. The committee recommended that the conclusions reached by the Committee on Ophthalmia Neonatorum of the American Medical Association be approved by the American Public Health Association, and that whenever practicable the Health Officer of the State or Territory over which he exercised jurisdiction be urged to confer with the committee appointed by the American Medical Association, and to inaugurate such measures through the State and its counties for the enlightenment of the people and the control of this disease as might in their judgment seem advisable. The recommendations of the Committee on Ophthalmia Neonatorum of the American Medical Association were (1) to secure the enactment of laws in each State or federal territory requiring the registry of births and placing the supervisory control and licensure of midwives in the Boards of Health, requiring that all midwives be examined and registered in each county, and that they be required immediately to report each case of ophthalmia occurring under their ministrations under penalty for neglect, if found guilty, of fine, and for a subsequent offense, forfeiture of license. (2) The distribution by Health Boards, through bulletins and otherwise, of circulars of advice to midwives and mothers, giving instructions as to the dangers, methods of infection and prophylaxis of ophthalmia neonatorum. (3) The preparation and distribution by the Health Boards of ampules or other receptacles containing the chosen prophylactic with specific directions for its use. It is advised that the choice of the prophylactic be determined by the health officer with the advice of the committee representing the obstetricians and ophthalmologists for that State from the American Medical Association. (4) To insist on the maintenance of proper records in all maternity institutions and other hospitals in which children are born, of the number of cases of ophthalmia neonatorum, with the method of treatment and the results. These reports, which should include all cases of scarred cornea as well as of blindness, should be filed at regular intervals with the Department of Public Health, and the records published. (5) Periodical reports to Boards of Health by all physicians engaged in obstetrics of the number of cases of ophthalmia neonatorum that has occurred in their practice within a specified time, whether or not a prophylactic was used, and if so, what, together with the result.

DR. GARDNER T. SWARTS of Providence, R. I., said that inasmuch as ophthalmia neonatorum was a communicable disease, the proper health authorities and health associations should take cognizance of that fact and endeavor to combat the disease as they did other communicable affections. In Rhode Island there was a law requiring that if inflammation of the eye or eyes occurred in a child during the first five days after birth, a physician or health authority should be sent for to take charge of the case. It was the duty of health officers, if they found that this disease was prevalent, to notify physicians of the fact, and particularly the younger practitioners. As the disease was a preventable one, such prophylactic measures as suggested by Dr. Lewis should be carried out.

DR. F. F. WESBROOK of Minneapolis said it should be a comparatively easy matter to convince the provincial or State authorities that what money was expended in providing for printing, postage, nitrate of silver, argyrol, or some other drug, was more than saved in the cost of providing for the education, housing and maintenance of blind people. He felt quite sure that in Minnesota they would save in the State Hospital for the Blind more than it would cost to carry out the recommendations of this committee.

DR. CHARLES F. FAGAN of Victoria, B. C., said that for a number of years he had devoted his entire attention to health matters and was ashamed to say that he had neglected his duty on this question, but in the future would endeavor to keep this subject before medical and health authorities, so that they would take action. He would certainly take up this question in his own district.

DR. WILLIAM HENRY GUILFOY of New York City said that steps had been taken by the New York City Department of Health in prosecuting successfully some of the midwives who had been accused of not reporting cases of ophthalmia among very young infants. The Health Department had found it necessary to go further, and at the last session of the Legislature a bill was passed which gave the New York City Department of Health complete power over registration and the practice of midwifery, and in consequence certain rules had been formulated, a violation of which was a misdemeanor and punishable by fine and imprisonment. Very soon they hoped to see the way clear to have about fifteen hundred midwives under constant supervision.

DR. JOHN N. HURTY of Indianapolis, Ind., said that all those who were engaged in public health work should fully appreciate the importance of this report and its recommendations. While great progress had been made in this regard, still it would be a long time before the legal authorities took hold of this matter in the right way, and it would be a long time before the people would become interested in that which concerned them so deeply. It was strange that the people themselves were so indifferent in regard to the prevention of blindness.

DR. HURTY moved that the Secretary be instructed to publish at the earliest date possible the report of the Committee on Ophthalmia Neonatorum in the *Journal of the American Medical Association,* or other medical journal, and that he should have 2,000 reprints made and distribute the same according to his judgment, subject to the approval of the Publication Committee.

This motion was seconded and carried.

Vaccination with Humanized Lymph.—Dr. FRANCISCO DE P. BERNALDEZ of Mexico described the methods adopted by the Vaccination Department of the Supreme Board of Health of Mexico, with the most satisfactory results. The region in which the vaccine was to be inserted, whether on the arm or on the leg, was carefully washed with sterilized water, soap and a brush, rubbing with the latter until the skin became red, and was then dried with sterilized cotton. The inoculation was then practiced with lancets that had previously been dipped in boiling water or passed through the flame of an alcohol lamp. The postules of the child from whom the vaccine was drawn were cleansed exclusively with sterilized water and cotton, were very superficially scarified, and not used if they bled. A small quantity was taken up on the lancet and the inoculation made in the person who was to be vaccinated by means of small punctures, almost joining each other, and six to eight in number. In making these punctures the lancet left the lymph spread over the place where the punctures had been made. These should not reach beyond the dermic layer of the skin, because that was where the lymphatic network was found abundant and fine. Moreover, this was the way

to prevent the vaccine postules from bleeding. The object in making the punctures in the form above described was to produce postules in a series, so that the collection of the lymph would be facilitated, because there would be only one scar and not several. The pustules might be numerous, and, lastly, the vaccination was not painful. The advantages of this method over others that had been described were that they did not cause any pain, did not give rise to any flow of blood; they facilitated the collection of the lymph, and they could easily be examined to find whether they presented the characteristics of true vaccination, because this was the only way in which the operating physician could ascertain with certainty whether a person had been well or badly vaccinated. If other methods were employed, or the skin was scratched, the pustules could not present those characteristics, and the operator always remained in doubt as to whether the individual had obtained immunity or not.

Prevention of Smallpox.—Dr. James Roberts of Hamilton, Ontario, described an outbreak of this disease which comprised some eighty cases, the handling of which cost the municipality of Hamilton approximately $10,000. The one feature which appeared to him more striking than any other in this outbreak was the precision with which the disease singled out in family after family the unprotected for attack. He was unable to find after careful scrutiny of the personal history of each case previous to this illness any evidence to prove that in more than one or two instances vaccination had ever been performed. Practically the whole series of cases was without the semblance of a scar. More thorough investigation and closer inquiry into the causes of disease furnished more convincing evidence in favor of contact infection as the chief factor in the spread of this as well as the other exanthemata, notwithstanding all that had been said and written on the doctrine of aerial transmission. The author believed that if the enforcement of the vaccination act were entrusted by law to the sanitary authorities alone, with the necessary legislation to protect them adequately in the discharge of their duty, the great bulk of the people of Canada would be found as willing to have the law carried out as were the people of Germany. Upon the practicing physicians devolved the great and serious responsibility of seeing that the performance of vaccination for contract prices among school children and among the industrial population in large cities was carried out in such a scrupulous and conscientious manner as in no wise to bring discredit or reproach upon the twenty years of quiet and painstaking investigation which gave to the world the greatest discovery known for the preservation of the human species.

Dr. W. F. Elgin of Glenolden, Pa., referred to the effect of heat on vaccine. Taking virus from the same animal and subjecting it to various temperatures and noting the results, the speaker found that a temperature exposure of 60 deg. C. killed the vaccine matter in five minutes. Where the vaccine was kept at the temperature of the body, and was carried by physicians in their pockets for three days, it had but little or no effect. At a temperature of 25 deg. C., or ordinary room temperature, vaccine would last a week; at a temperature of 15 deg. C., it would last from three to six months, and if kept below the freezing point, minus 10 to 15 deg., he had been able to keep it for four years, and it was good at the end of that time. But he had never kept vaccine longer than that.

Dr. F. M. Smersh of Owatonna, Minn., said that in order to have a successful vaccination, the arm, the towel, and the vaccine must be aseptic. He found in a great many instances that people who had been vaccinated infected themselves through carelessness. In many cases they put a dirty rag around the sore. He cited some instances where infection had occurred.

Dr. Alton S. Fell of Trenton, N. J., referred to the methods of quarantine in cases of smallpox. Prior to seven years ago the speaker had not seen a case of smallpox. In December, 1901, the disease broke out in the city of Trenton, and the President of the Board of Health, who had had some experience with smallpox, insisted that no matter what the stage of the disease was, everyone should be taken to the Isolation Hospital, and isolated for a period of eighteen days. This worked a good deal of harm, and later such rigid isolation measures were not enforced, but the results were equally as good.

Dr. William A. Evans of Chicago said there was a growth of anti-vaccination sentiment in this country which he believed philosophically was founded on the prevailing principles of American law. In addition, it was founded upon a growing diminution in the virulence of the disease, due largely to the fact that men protected were modifying the causative agency of smallpox just as the causative agency of smallpox in turn modified man. He believed that this decreasing virulency of the disease was a factor in the development of an anti-vaccination sentiment which proved ill for this country. Some organization should prepare a refutation of the arguments advanced by anti-vaccinationists, and this refutation should be given the official endorsement of the organization responsible for its preparation. He knew of no organization that was better prepared to do this work than the American Public Health Association. Accordingly, he moved that a committee be appointed to prepare an argument as to the efficacy of vaccination, and that the association devise some means for the dissemination of that report, and that some effort be made toward a simultaneous and concerted movement throughout the country in opposition to the anti-vaccination sentiment.

This motion was carried, and a committee of seven was to be appointed by the President.

Dr. L. Laberge of Montreal said that in 1885 they had a serious epidemic of smallpox, having had 10,000 cases in eleven months. They struggled with this epidemic by means recommended, namely, vaccination and isolation. Since then they had tried to have a compulsory vaccination act in the city, but had not been able to obtain it. But they had, however, an ordinary which held the employer and the superintendent of schools responsible. They had now power to vaccinate, and since that time vaccination had been very efficacious. They had no hesitation in isolating a case from the first hour of making the diagnosis.

Address of the President.—Dr. Richard H. Lewis of Raleigh, N. C., pointed out the difficulties in the way of establishing a national department of public health in the United States by the dual nature of the government and the distribution of constitutional powers. It was unquestionably to the interest of the general cause that each State should look after its own health work, acting always in a spirit of cordial cooperation with the great national bureau, which spirit the latter should be very careful to foster and encourage in every way, not only to its own interests, but that of the whole country. It would not be at all difficult to so conduct the national bureau as to have the State Boards look to it as both guide and friend. In a general way, the kind of national bureau of health we ought to have and the kind he thought most desired, was one including within its scope and management all the specific health agencies of the government now in existence, with the addition of others when needed, so thoroughly manned by the best men in their respective departments, and so richly endowed with funds that work of the highest class in demonstrating the principles underlying all subjects bearing upon the public health could be done. Having by the study of the work of others and by original research settled upon the correct principles of sanitation, it should make a practical application of them to the actual everyday problems of preventive medicine in the sanitary management of the District of Columbia and the territories over which the United States had absolute control. It should give a clinical demonstration of the best methods as carried out by its own thoroughly educated and trained health officers. But it was as a source of information and education that we found the chief value of the bureau.

First, in the education of its own officials and the health officers of the country; second, of the medical profession, and, third, of the people. In a bill now pending in Congress further enlarging the powers and duties of the Public Health and Marine Hospital Service, authority was given for the establishment of a school of hygiene for the training, free of charge, of such health officers as might choose to attend. The granting of a certificate was allowed, but it should go further and grant the degree of Doctor of Public Health, as was done in England. In this way we might hope for the gradual development of a sanitary profession of equal dignity with that of medicine or the other regular professions.

Typhoid Fever in the Province of Manitoba.—Drs. R. M. Simpson and A. J. Douglas, in a joint paper on this subject, directed their attention in particular to Winnipeg. Separating Winnipeg into two parts, North and South, they found in the south district, where nearly all houses were furnished with improvements, 549 cases of typhoid in the years 1903-4-5. In the north district, where box closets dotted the landscape at frequent intervals, during the same period there occurred 1,983 cases. Particularly striking was the fact that as soon as the evenings began to grow cold in August, and the flies were driven indoors, the typhoid rate rose, and when the first hard frosts of winter set in, and the snow fell early in November, a diminution at once took place. Box closets offered every possible facility for flies to act as infection carriers, the excreta being above ground and entirely accessible, and the light not excluded. It was the commonest thing not only to see flies swarming in these places, but also to see abundant evidence of their actually breeding in them. It was a frequent occurrence to visit houses and find two or three typhoid patients being cared for in one room where the cooking was done and the food kept, the individual who was doing the cooking usually acting in a nursing capacity as well. Drastic regulations were undertaken. No case of typhoid was allowed to remain at home unless the conditions were such that proper isolation could be obtained, and that excreta could be handled in a manner precluding the chance of infecting others. Rigid disinfection of the premises was carried out in all cases. The use of metal garbage receptacles was insisted on, also that manure should be kept in covered boxes and removed frequently and regularly to avoid affording breeding places for flies. The Provincial Board of Health and the Local Department distributed literature on typhoid prophylaxis and on the care of cases. Circulars were issued instructing people to screen their houses and to keep down the number of flies by the use of flypaper and other means. Milkmen were instructed as to what their duties were. Careful supervision was exercised over the water supply, and a large number of public and private wells had been closed. Low lots were drained or filled in, rubbish heaps were burned or destroyed, lanes paved or graded, many insanitary premises were closed altogether, and work along these lines was still going on. Last year some results from their efforts were evident, and from indications the present year would exhibit an even more satisfactory showing, as up to the present they had only had 160 cases, which was considerably less than last year's total at the same time.

Epidemiology of Typhoid Fever.—Dr. H. W. Hill of Minneapolis traced the history of typhoid fever from the earliest stage to the present time. In old times it could be attributed to flies and to the mother of the child. Contact and fly contamination were the great causes of the spread of the disease. The Minnesota State Board of Health issued the following instructions with regard to typhoid fever: "To the Citizens of ————: Typhoid fever is epidemic in ————. The Minnesota State Board of Health is investigating this epidemic to find its exact source. Meantime, govern yourselves as follows: 1. Typhoid fever is contracted solely by the mouth. If you do not put the poison of typhoid fever into your mouth, you will never contract the disease. Therefore, watch the mouth. 2. Do not eat or drink anything (water, milk, oysters, fresh vegetables, or anything else) unless it has been first boiled, broiled, baked, roasted, fried or otherwise thoroughly heated through and through. 3. Do without all food or drink which has not first been thus heated. (Canned or bottled foods or drinks, other than milk or water, are not included in this.) 4. If living in the same house with a typhoid fever patient, do not handle your own food or food intended for anyone else, even if it has been heated, except with hands that have been thoroughly washed with soap and very hot water, preferably also with antiseptics. Ask your physician about the antiseptic to use. Wash before every meal in this way and before cooking, serving or eating anything or putting the fingers in the mouth. 5. If there are flies about, see that all food and drink is protected from them at all times. Flies often carry typhoid poison to food and drinks. 6. The poison of typhoid fever does not show itself for two weeks after it enters the body. Therefore, for the next two weeks, typhoid cases may develop from typhoid poison already taken in. But any case which develops on and after (a date two weeks later than the date of the placard) will be due solely to neglect of this notice and failure to carry out minutely the directions here given."

Dr. John F. Anderson of Washington, D. C., agreed that flies were a fruitful source of infection. Milk was also a source of contamination, due to the lack of proper washing of the cans and other causes.

Dr. Henry Albert of Iowa City, Iowa, exhibited a table showing the epidemics that had taken place through the carriage of bacilli from infected places, the period of infection extending over several years before the disease made itself known. An interesting case was reported early in the present year from Germany, in which thirty-two cases of typhoid fever developed among a population of 130. The author referred to one case in which for fifty-two years a woman had been a carrier of typhoid bacilli, and was the cause of an epidemic which prevailed last year. She was the keeper of a hotel. Women and children were the greatest carriers of the disease. One in every 500 adults who had never had typhoid were chronic carriers. It was impossible to state how long the bacilli carriers acted as such, but it was certain there were as many carriers as there were cases of the disease. Many cases were to be traced to the gall-bladder. He expressed the opinion that in a few years there would be sufficient knowledge to prevent the carriage of the disease, and that one of the greatest preventives would be vaccination.

A Study of Typhoid Fever in Richmond, Va., with Certain Conclusions Relating to the Disease in the South.—Dr. Ernest C. Levy and Dr. Allen W. Freeman of Richmond, Va., in a joint contribution on this subject, pointed out the importance of reporting promptly all cases of typhoid fever by the physician in attendance. There were recommended:—Freer use by physicians of the laboratory aids to diagnosis, which were now furnished gratis by all progressive city and State Boards of Health. Immediate inspection of every reported case, the securing of full information and the study of the data so obtained, with the view of determining the origin of the case. Instruction of the members of the household, at the time of this visit, in the elementary points in the epidemiology of the disease, and leaving printed directions covering the same points. Extension of the sewerage system, so that dry closets may be entirely abolished. Pending this, rigid rules, rigidly enforced, governing the construction and maintenance of dry closets in those sections which were forced to rely on this primitive means of disposal of excreta. The closing of all wells in the city, when a good public water supply was available, and the extension of this supply to reach all the people. Thorough dairy inspection, and the rigid enforcement of a rule requiring every dairyman, under penalty of revocation of his permit, to report immediately any case of illness among the members of his household, as well as among his em-

ployees and their families. Prompt investigation of such reports by the Health Department, and the temporary shutting out of the milk wherever a typhoid case that could not be perfectly isolated was found. Rigid supervision over the disinfection of excreta in all typhoid cases, and the supplying of disinfectants gratis by the Health Department in indigent cases. The campaign against flies, the limiting of their breeding places, and the screening of all typhoid cases, on the one hand, and living rooms, dining room, and kitchen, on the other. Supervision over "carrier" cases, although just how this could be done legally and efficiently was at present an unsettled problem. Education of the public and the medical profession by lectures and literature on the main points of typhoid prophylaxis, especially in regard to the hygiene of the sick room and the danger of carrier cases. If the greater part of southern typhoid is of the residual type, the above measures constitute, in the light of present information, the chief means of lowering the typhoid fever death rate in the South generally.

The Commercial Pasteurization of Milk.—Mr. B. R. Rickards and Mr. W. M. Campbell of Boston said that a large amount of milk was pasteurized in Boston every day. Some of the milk of one contractor was pasteurized in the country and was again pasteurized here. The amount of milk pasteurized was probably increasing. It was evident that the larger part of the milk now pasteurized was before pasteurization above the limit established by the Board of Health of Boston, 500,000 bacteria to a c.c. Some of this milk was of very high bacterial content. Bacteria would increase much faster in pasteurized than in unpasteurized milk. Souring bacteria were killed out quicker by pasteurization than other forms. The tendency was, therefore, for such milk to remain uncurdled much longer than unpasteurized milk, the milk thus having a chance to putrefy. The pasteurization of milk affected the microscopic estimate of bacteria and leucocytes. The authors concluded (1) that the commercial pasteurization of milk without restriction put a premium on dirty milk, since dirty and old milk, otherwise unsalable, could then be put on the market. (2) Pasteurized milk might well mean cooked dirt, cooked dung, and cooked bacterial products, and the laboratory was powerless to detect it. (3) The commercial pasteurization as at present practiced in Boston probably would destroy all disease-producing organisms with the possible exception of the bacilli of tuberculosis. The latter would probably be killed in the majority of instances. One machine only out of the three tested would be likely always to destroy the latter. The toxins produced by these and by the putrefactive organisms in dirty milk would undoubtedly escape unharmed and in many cases be capable of producing severe intestinal disturbance, especially in babies. (4) A false sense of security was undoubtedly conveyed by the term pasteurized milk. The lack of security might come from either improper pasteurization, the pasteurization of improperly handled milk or improper care of pasteurized milk. (5) The unrestricted pasteurization of improperly kept, old or dirty milk should be prevented by regulations or ordinances prohibiting the pasteurization of milk containing over a certain specified number of bacteria per cubic centimeter, the bacterial limit being set with due regard to local conditions, especially the distance from which the milk comes. Such regulation should, of course, be coupled with a regulation forbidding the sale of milk above the bacterial limit established. (6) The law should require that milk heated above 140 deg. F. should be marked "Heated or pasteurized milk." Pasteurized milk should not be sold as fresh milk. The pasteurization of milk in itself was probably not a harmful process and was to a certain extent a necessity under modern conditions in large cities, but commercial pasteurization should be carried on only under the most stringent supervision.

Result of Reincubation and Reinoculation of Atypical Diphtheria Cultures.—Mr B. R. Rickards, Mr. F. H. Slack and Dr. B. L. Arms of Boston presented the results of reincubation and reinoculation of 242 atypical cultures, proving that in many instances a final result may be obtained by these means and a report sent to the physician before the result could be obtained from a secondary culture. Of 242 such cultures, 120 proved either from these or subsequent cultures to be positive; 82 proved to be negative; no subsequent cultures were received on the other 40, although requested. Of the positive cases, reincubation was positive and reinoculation negative in 20 instances. Reincubation was negative and reinoculation positive in 16 instances. Both were positive in 43 instances. Both were negative in 41 instances, the subsequent cultures being positive. The results tended to show that the diagnostician who reported positive or negative only was likely to be in error in about 50 per cent. of those cultures which contained atypical forms only. It was preferable in such cases to report "suspicious organisms present," request another culture, and do further work with the culture already obtained. In many instances positive results were obtained from such cultures after but five to seven hours' additional incubation.

Report of Committee on Standard Methods for the Diagnosis of Rabies.—The committee gave a summary of its knowledge in regard to the diagnosis of rabies. In consideration of the fact that there were still many unsettled questions in regard to this subject, the committee recommended as a working method to use in diagnosing rabies the following: "1. Removal of central nervous system and of salivary glands under aseptic conditions. 2. Smears or impression slips made from ammon's horn, fixed in neutralized methyl alcohol, and stained over the flame until steamed, with the following solution: Methylen blue, sat. alc. sol., 30 c.c.; fuchsin, 5 c.c.; dist. water, 300 c.c. (to be kept in icebox until used)."

If typical Negri bodies were demonstrated, the diagnosis of rabies could be made; if they were not found, similar slides should be made from the gray matter: (1) Of the cerebellum, (2) of the cerebral cortex (motor areas), (3) of the gray matter from other areas. At least six slides should be made, covering a wide area of gray matter in order to exclude the possibilities of localization of definite Negri bodies. If no Negri bodies or suspicious forms were found in any of the slides, and the examined material was fresh, the diagnosis was probably not rabies. If suspicious forms were found in fresh material, the diagnosis was probably rabies. If no definite forms were found in decomposing brains, the diagnosis doubtful must be given. In all cases where the diagnosis was uncertain, animals should be inoculated with a fine emulsion made from material taken from various parts of the brain and pieces from surrounding parts should be prepared for sections. Pieces should also be taken from the Gasserian and several spinal ganglia for demonstrating the presence of the rabies tubercles, as well as of the Negri bodies. Two rabbits or four guinea pigs should be used for the inoculation, which might be either subdural or intracerebral. The inoculated animals should be kept under observation for at least three months before a negative diagnosis was made. An emulsion from different parts of the brain should be made in sterilized neutral glycerin for later inoculations, if, for any reason, the first should be unsatisfactory. Decomposed brain should be allowed to remain in the glycerin for one to three weeks before inoculation, unless very weak solutions were used. In the latter case negative results would necessitate another inoculation.

Animal Inoculation in Tuberculosis, Rabies, and Glanders.—Dr. B. L. Arms of Boston presented some of the unusual results from animal inoculation in one case of tuberculosis, three of rabies, and six of glanders, all occurring in routine work, with the following conclusions: (1) All pigs inoculated for tuberculosis should be

autopsied. (2) All negative rabies pigs should be kept under observation for twelve months. (3) All negative glanders pigs should be kept under observation for at least four weeks. (4) All pigs inoculated for glanders dying after forty-eight hours should be autopsied. (5) Any inoculation might give a freak result, consequently the possibility of the unusual occurring in any given case must be remembered.

Committee on Standard Methods of Chemical Analysis for Water and Sewage.—The committee (Earle B. Phelps, Robert S. Weston, Edward Bartow, A. Elliott Kimberly, L. P. Kinnicutt) had been at work collecting information looking to a revision of the present standard methods. A circular letter was sent out to water chemists and others. The present standard methods were in quite wide use, and no very important changes were suggested. Some additional matter was needed, particularly in the case of mineral analysis of water, and of the analysis of alum and other materials used in water and sewage treatment. The committee had planned a comparative study of all alternative methods and modifications, which would be undertaken by the various laboratories volunteering. The final form which the various methods should assume would be determined by the results of the proposed study. Changes were proposed in the following determinations, some of the changes being only in minor points: Turbidity, free ammonia, organic nitrogen, nitrates, copper, hardness. Additional methods were planned as follows: Complete mineral analysis, the determination of manganese, free chlorine, alum, and other commercial products.

Stability and Putrescibility in Sewage Filter Effluents.—Mr. Earle B. Phelps of Boston said that the development of the modern rapid sewage filter had given a somewhat altered conception of the function of sewage disposal in general, and the rapid introduction of such filters had necessitated changes in the schemes of sewage analysis and their interpretation. The most important result of all this was that they looked now for qualitative changes, rather than quantitative removal. The putrescibility test had become a most important one. The author dealt with the subject of putrescibility with a view to arriving at a definition which would be acceptable to all, a method or methods of determining putrescibility which would harmonize with that definition, and a method of expressing results so that they shall have quantitative significance. Putrescibility was shown to mean ultimately the availability of the material as a bacterial food. To avoid confusion and confliction of the present conceptions with various past uses of the term, it was recommended that the word stability would better represent the thing sought after in sewage purification. Stability was shown to be not an absolute characteristic to be recorded as plus or minus, but a relative and quantitative property of organic matter, which required quantitative treatment. The methylen blue or similar test was recommended for adoption as a standard test. It combined great simplicity with quantitative accuracy, a combination possessed by no other test. Finally the speaker also proposed a method of recording results by which the time required to decolorize methylen blue could be properly weighted to give a stability factor which was an accurate index of the quality of the effluent.

State Control of Public Water Supplies.—Dr. C. O. Probst of Columbus, Ohio, said that if a polluted public water supply concerned only the community that used it there might be some argument in favor of home rule, although in this case it would be more properly home misrule. The State had become in a large measure one community, and it must assume increased responsibility for the conditions which threatened the lives and health of the people. It should be the duty of the State to protect from pollution, as far as possible, all sources of water supplies of which use was being made. The question coming up in all populous States was, Could the streams and watersheds that must furnish public water supplies be kept free from contamination by laws and inspection? This might be possible for some of the States, but not for the great Middle West territory, where usually municipal and industrial wastes must go to the streams. Should these wastes be purified in all cases where the stream was used in any part of its course as a public water supply, or should water purification be depended on for protection? We could not settle this problem for all communities in general terms, for the very evident reason that each community afforded a problem of its own. The State should decide what could best settle such questions.

Means to Promote the Health of School Children.—Dr. M. L. Price of Baltimore began at the cradle and ended at the grave. Among other things, he said that school education was important. The first education of the child should be to save itself from death. Teachers should carefuly instruct the children in methods of hygiene. There should also be medical inspection of the schools. Children were subject to many diseases. They should not be allowed to exchange food or clothing, or any article of personal use.

Dr. Samuel G. Dixon of Ardmore, Pa., strongly urged the vaccination of children before they would be allowed to attend any school, public or private, and said that all schools should have a regular medical inspection and regular disinfection.

Registration of Births and Deaths.—The following resolution was adopted:

Resolved, That the draft of a model law for the registration of births and deaths in the United States, based upon the essential requirements of registration, as laid down by the American Public Health Association in conjunction with the United States Bureau of Census, and approved by the American Medical Association and by the conference of Commissioners on Uniform State Laws, be cordially endorsed by the American Public Health Association; and that the Committee on Legislation of the Section on Vital Statistics be authorized to cooperate on behalf of this association with the representatives of the other organizations named and with the Bureau of the Census in making such minor changes as might be necessary and in urging the adoption of such legislation in non-registration States.

Enlarging the Powers of the Public Health and Marine-Hospital Service.—The following resolution, introduced by Dr. John N. Hurty of Indianapolis, Ind., was adopted:

Resolved, By the American Public Health Association, that it heartily recommends to the American Congress the passage of such legislation as is intended to enlarge the scope and increase the efficiency of the Public Health and Marine Hospital Service. To this end the association believes the powers of the service should be increased; that provisions should be made for the retirement under pay of the members of the service, and that the salaries of the said members should be made commensurate with the medical service of the army. The Secretary shall send a copy of this resolution to the chairman of the House Committee on Interstate and Foreign Commerce, and to the corresponding committee in the Senate.

Officers.—The following officers were elected for the ensuing year: *President,* Dr. Gardner T. Swarts, Providence, R. I.; *First Vice-President,* Dr. R. M. Simpson, Winnipeg, Manitoba; *Second Vice-President,* Dr. Jesus Chico, Mexico City; *Third Vice-President,* Major Charles F. Mason, U. S. Army, Washington, D. C.; *Secretary,* Dr. Charles O. Probst, Columbus, Ohio; *Treasurer,* Dr. Frank W. Wright, New Haven, Conn.

Richmond, Va., was selected as the place for holding the next annual meeting; time to be fixed by the Executive Council.

AMERICAN PEDIATRIC SOCIETY.

Twentieth Annual Meeting, Held May 25 and 26, at Delaware Water Gap, Pa.

PRESIDENT DR. CHARLES G. KERLEY IN THE CHAIR.

Special Report to the MEDICAL RECORD.

(*Concluded from page 569.*)

Tuesday, May 26—Second Day.

Public School Education.—Dr. CHARLES GILMORE KERLEY of New York delivered an address with this title. He considered his subject of public school education as it affected the physical and mental development of the child. There were at present 18,000,000 children in the public schools of this country, and they now attended school ten months of the year, five days a week, and five hours a day; therefore a large part of the responsibility of rearing these children that had formerly belonged to the parent fell to the schools. These children were compelled to read and to write more or less during the time they were in school and by an artificial light. The question arose, what had these schools taught the children? Had they fitted them to compete for a living? It had been shown that a large percentage (from 17 to 80) of the pupils in the public schools were defective. Formerly the children in the schools were mostly English speaking and now this was not the case. In the larger cities there were from 75 to 90 per cent. foreign-born children. The school system was seriously at fault in not teaching something of sex. Dr. Prince A. Morrow was authority for the statement that 75 per cent. of the population either have or have had gonorrhea and that from 10 to 14 per cent. had contracted syphilis. Sixty per cent. of the morbidity among the male population was due to these infections. Thirty-five per cent. of the blindness was due to gonorrhea, and from 60 to 80 per cent. of the pelvic disorders of women were due to the same disease. Dr. Kerley said that he had known three girls who became pregnant in their thirteenth year and all of them were ignorant of the nature of the sexual relation. It was evident that the children were being educated to the danger point. The competitive spirit was pushed to its limit and the whole atmosphere was charged with the inevitable causes of disappointment, failure, and suicide. The overeducation of the unfit brought forth tastes, traits, and desires that he should never have known of and was the cause of much dishonesty. Sons of trades people no longer would follow the calling of their fathers; all wished to become professional men and bank presidents. Dr. Kerley thought it would be wise to insert into the curriculum a few minutes' talk on the nobility of labor and to emphasize the fact that all labor was honorable except that which was badly done. Children had the right to demand better physical advantages than they were receiving at the present time. If they were to judge the public school system by the manner in which it discharged its duty in these directions they would have to admit that it had failed in its function.

An Unusual Type of Nephritis in Children.—Dr. JOHN LOVETT MORSE of Boston said that he had recently seen a number of cases of acute nephritis in children that differed from those one usually met with in that there was almost complete absence of blood and blood elements in the urine. There were large numbers of round mononuclear cells, often associated with polymorphonuclear leucocytes. The comparatively large diameter of the casts was also observed. He cited a number of cases to illustrate this type of the disease. In these the amount of blood present had been moderate in the beginning and had disappeared after a few days, and then the urine took on the characteristics mentioned. He thought the cases were milder in character and of shorter duration than ordinarily seen, and the prognosis was better. He said he had never had an autopsy in one of these cases.

Dr. HENRY KOPLIK of New York said that the paper had reminded him of certain cases of typhoid fever in which such kidney trouble occurred, where there were leucocytes and casts in the urine. It was difficult to distinguish these cases from infectious nephritis. In cases of gastroenteritis followed by nephritis there was a question of the involvement of the ureters and bladder, especially in female children.

Dr. J. H. MASON KNOX of Baltimore mentioned a case of this kind in which there was hematuria, a number of leucocytes, and a few casts. The kidneys at autopsy showed the convoluted tubules undergoing hyaline degeneration.

Dr. L. E. LAFÉTRA of New York spoke of a case that had been under his care in which the leucocytes persisted long after the disappearance of the casts. He had been unable to account for the condition, as the child was otherwise in good health.

Recent Diagnostic Methods in Children.—Dr. L. EMMETT HOLT of New York presented charts to show the fever reactions to tuberculin, the tuberculin eye test (Calmette), and the tuberculin skin test (von Pirquet). Of the fever reaction to tuberculin, of the positively tuberculous, 22 were positive, one was doubtful, and one was negative. Of the cases probably tuberculous, there were 17 positive, and no doubtful or negative reactions. Of the cases probably not tuberculous, there were two positive reactions. Of the positively nontuberculous, one gave a positive reaction, and there were 60 negative reactions. There had been no bad results among the 568 tests made. Of the tuberculin eye test (Calmette), of the positively tuberculous there were 24 reactions, three doubtful reactions, and eight negative reactions. Of the probably tuberculous cases, 15 were positive, and one was doubtful. Of the probably nontuberculous, there were two positive reactions, six were doubtful, and 508 were negative. Of the tuberculin skin test (von Pirquet's), of the positively tuberculous, seven were positive, and one was negative. Of the probably tuberculous, seven were positive, and one was negative. Of the probably tuberculous, nine were positive, and one was negative. Of the probably nontuberculous, there were 41 negative. Of the positively nontuberculous, three were negative.

Dr. WILLIAM P. NORTHRUP of New York said that he had reached the same conclusions as Dr. Holt. He had carried out the injection test in 65 adults under the direction of Dr. Trudeau. The patients were made quite ill and he could not take quite as cheerful a view of the test as Dr. Holt did. Dr. Baldwin of Saranac Lake had suggested that there should be three points of scarification in carrying out the skin test. He used a small instrument much like the screw driver used for eyeglasses. He used broth for the first; broth plus old tuberculin 5 per cent. for the second, and plus tuberculin 10 per cent. for the third.

Dr. THOMAS MORGAN ROTCH of Boston described the work that they were doing along this line. He described at length the advantages that they had in the way of material for experiment. He was of the opinion that the eye and skin tests would be more popular than the fever test in the future because there were a large number of cases in which we were doubtful whether we were dealing with tuberculosis or not. There was such a large number of cases in which this test could not be used. He thought that perhaps where it could be used it gave better results than the others. He had never had any serious results with the fever test excepting where a gross error was made.

One should be very careful as to the dosage. He had had best results with the eye test. They had given it in 100 consecutive cases and it seldom gave a reaction except where there was tuberculosis, and in almost every case it disclosed the tuberculosis. He hoped that the skin test could be used because it gave more rapid results. They had given small doses frequently repeated in their experiments. It was better when repeating the eye test to repeat in the other eye.

Dr. Augustus Caillé of New York said that he was opposed to the eye test. The eye was not the proper organ for experimentation. The tuberculin test had been found to fail in 5 per cent. of the cases upon which it had been tried. He thought the test fairly unreliable and was opposed to it in a general way.

Dr. Henry Koplik of New York said that he used the v. Pirquet test in those cases where there was fever and the tuberculin test was ruled out. He had used 1/10 mg. and then increased the dose as indicated. He expected to publish the results at the Tuberculosis Congress. He had not allowed the eye test to be used in his service. He related an instance in which the eye test had apparently failed and a family had been thrown into a panic by the announcement that the child had tuberculosis. The child recovered in a very short time, with no signs of the disease. Of course, one could not tell what would develop later.

Dr. S. Mc. Hamil of Philadelphia had used the eye test in 177 cases and had had his preconceived prejudices confirmed. His work had been on institutional children and he had had some very disturbing results. In 144 cases he employed the cutaneous test and the ointment test of Moro. He had employed the eye tests first, following that the ointment test, and then he took the balance of the cases and employed the three tests at the same time. It was evident that there was practically no difference in the reaction of these tests. There was uniformity of degree as well as uniformity of action. The reaction with the cutaneous test was most marked in 35 per cent. of the tests; in 34 per cent. it was most marked with the eye test; with 24 per cent. most marked with the ointment test. He had employed the cutaneous test in confirmation of the others in 85 per cent. and the results were positive in all but one case. He used 1/10 mg. and repeated it in 25 per cent. of the cases. The dose was advanced to 1 mg. if necessary. He was working in an institution that was overcrowded and had a definite number of cases of definite tuberculosis. This accounted for the high percentages. In 20 cases he had used both human and bovine tuberculins. In eight cases the reactions were the same to both. The reaction was more marked to the bovine than to the human in two cases. He had anticipated this result because the bovine tuberculin was much weaker than the human.

Dr. A. H. Wentworth of Boston spoke of the German statistics that gave a number of reactions in healthy persons. He asked how they proved the so-called healthy persons to be nontuberculous.

Dr. Holt, in closing the discussion, said that Dr. Park made no deductions when one man used ½ per cent. and another 1 per cent. tuberculin. There was so much difference in the strength of these tuberculins that the results could not be compared. He said that statistics had recently been given comparing the results of tuberculin tests with the findings at autopsies, the point being to determine the latent tuberculosis. These statistics threw some light upon the positive reactions in healthy persons. The latent tuberculosis steadily rose from the first few months to past 14 years. If a positive reaction was obtained one should be very careful to ascertain if the patient had tuberculosis. The sputum should be studied, going over it again and again. The fact that we got a positive reaction in a patient and that the patient got well did not prove that the case was not one of tuberculosis.

Fresh Air in the Treatment of Disease.—Dr. Wm. P Northrup of New York read this paper. Two points of value he said he wished to bring up with regard to the fresh air treatment of disease: first, the practical application of the fresh air treatment, and, second, in what particular cases this method was to be adopted. The element of cold in the fresh air treatment was of value. He told of the experience of treating the tuberculous insane in New York City. They lived and slept better in the open air and it was not necessary to resort to drugs to produce sleep and to quiet them. The fever and the maniacal excitability of these patients were controlled. In the application of the cold fresh air treatment one of the first rules should be to make the patient, as well as the attendant, comfortable. Dr. Northrup then detailed the method of making a bed; a point aimed at was to prevent the cold getting up from below. The diseases that he had treated in the open air were pneumonia, scarlet fever, and other pyrexial diseases. Dr. Lambert of New York claimed that the open-air treatment of lobar pneumonia in adults shortened the course of the disease. The open air treatment killed no one; it did not even hurt anyone. In all the doubtful and desperate cases the treatment with fresh cold air determined the balance in favor of a cure in every case.

Fresh Air in the Treatment of Disease.—Dr. E. E. Graham of Philadelphia said that for eight years they had been using the fresh air treatment of diseases in the Philadelphia Hospital. Hospitalism he believed to be due to lack of fresh air. When this treatment was begun, the infant mortality immediately began to lessen. Of all the factors that went for reducing infant mortality, fresh air was one of prime importance. During the past three years he said he had been treating all the severer cases of pneumonia in children of all ages in the fresh air. The results had been so different from those under the old plan that he now had lost the dread of pneumonia as a hospital disease. Rickets, scrofula, gastrointestinal diseases, and many other diseased conditions had been much benefited by this method of treatment.

Dr. Augustus Caillé of New York said that he agreed with everything the essayists had said. Twenty years ago, when he entered the babies' ward, he tried to get the ladies in control to understand the importance of fresh air. At present they had a roof garden part of which was open and part closed. Breathing fresh air was the most important therapeutic agent we had.

Dr. A. Jacobi of New York said that in 1870 he proposed boarding out infants and taking the curtains from their cribs, and he proved that of every 100 infants admitted to the hospital and kept three months 100 died. He was asked to resign. Times had changed. He said that since immigration and poverty had increased we had a great deal more rickets than formerly. He thought the disease was due more to bad air than to bad feeding. The northern Russians and Swedes had rickets in their best families because their winters were eight or nine months long and the babies were not removed from their close quarters.

Dr. R. G. Freeman of New York related his experience with measles. In 1907 they had 71 cases in the Nursery and Child's Hospital and only one death. They had considerable otitis media and some pneumonia with the measles. Afterwards the whole ward came down with bowel trouble; the children were put outdoors and there were no deaths at all. Scarlet fever broke out in one of the measles wards, and they put 11 of the measles patients out on a closed piazza. They all did remarkably well. He, too, had felt convinced that rachitis was a disease of asphyxiation. The fact that it was a disease of winter,

that cases were better in the fall, that experiments on animals to produce the disease with different kinds of feeding had failed all pointed to the truth of the statement that it was a disease of bad air.

Dr. J. P. Crozer Griffith of Philadelphia said that there was a difference in the way that men used the term "fresh air." They sometimes meant breathing fresh air, sometimes breathing cold air, and sometimes exposure of the body to cold air. Exposing a child with a temperature of 107° to cold air to reduce temperature was a different thing from breathing cold air. There could be no discussion as to the advisability of breathing fresh air, but none of us would put a child in a cold room and take the covers off of it.

Dr. E. M. Buckingham of Boston said that he had intended saying just what the last speaker had said. Pneumonia patients suffering from dyspnea were relieved by placing them out in the air when the administration of oxygen failed to give relief.

Dr. C. B. Putnam of Boston said that when he first entered the Massachusetts Infant Asylum, 35 years ago, they were just beginning to farm out the children, but that since that time this method had developed until now they had less than 25 out of 125 children in the institution itself. There were some cases better suited to hospital treatment.

Dr. L. E. La Fétra of New York said that one could often overcome the objections to fresh air in private practice by using the inside awnings, which allowed the child to breathe fresh air without being exposed.

Dr. Charles G. Kerley of New York said he had been particularly interested in the fresh-air treatment of typhoid fever. He had had very little trouble in applying it in private practice. He thought that the teaching concerning tuberculosis had prepared people for the rest. No doubt deficiency of oxygen had much to do with rickets, but children got rachitis under the best of conditions, and he believed it essentially a nutritional disorder.

Dr. Samuel S. Adams of Washington said that farming out infants at the present time meant something very different from what it did at the time to which Dr. Jacobi had reference. They used at that time to farm children out to a darkey with five or six children of her own who would express surprise that the infant could not keep "pot liquor" on the stomach. He had been surprised at the willingness of even the ignorant to follow out directions in the fresh-air treatment. He cited a case in illustration of this.

Dr. F. S. Churchill of Chicago thought that people were more willing to carry out the fresh-air treatment than the profession at large believed. He had no difficulty in private practice and had a nurse follow up his dispensary cases, going to the home to look after them.

Dr. P. J. Eaton of Pittsburg said that the nurse had a great deal to do with results from this treatment. Dr. Northrup's famous paper "23" had given him the inspiration to teach the nurses, and he had been lecturing to them in four different hospitals.

Dr. L. Lovett Morse of Boston said that they had heard a great deal about fresh air and cold air for babies, and he wished to remark that it did no harm to well ones.

Dr. A. Jacobi of New York said that it had been suggested that the time to which he had referred when he spoke of farming out babies was different from the present, and he wished to say that it was hardly forty years ago, and many of the principles of good infant feeding were known then. He taught the same things at that time that he still taught. The Department of Charities of New York City had commenced at that time to board out children. The results were the same in institutions to-day as they were at that time. He was glad that common sense was beginning to prevail.

Dr. E. E. Graham of Philadelphia, in closing the discussion, said that, as he had pointed out in his paper, the importance of fresh air was recognized in the early part of the nineteenth century as an absolute necessity. When in 1864 the advisability of erecting a foundling hospital in Philadelphia was discussed such a step was decidedly opposed and Dr. Jacobi was quoted at that meeting. These methods had been taught by a few men for a great many years, but we were just beginning to get to them as a body. If we were as enthusiastic in our efforts to secure fresh air as we had been in securing clean milk we would get excellent results.

Dr. Northrup, in closing the discussion, said that he wished to emphasize what Dr. Graham had said in regard to paying as much attention to fresh air as we had to the quality of milk. He spoke of what agitation had done in the way of procuring a better quality of drinking water. He had purposely spoken concerning pneumonia and its treatment in the open air. He thought the body breathed the air and needed the stimulus as much as the lungs. He said that he was not at all sure that cold air would take the place of the bath in typhoid fever. Dr. Oliver Wendell Holmes had said:

"God lent his creatures light and air and waters open to the skies;
Man locks him in a stifling lair and wonders why his brother dies."

Dr. Henry D. Chapin of New York said that he had felt for a great many years that we had not lived up to our lights on this subject. We had seen hundreds of babies slip through our hands in these institutions without having the moral courage to tell the truth as Dr. Jacobi had.

Congenital Obliteration of the Esophagus with the Report of a Case.—Dr. J. P. Crozer Griffith and Dr. R. L. Lavenson of Philadelphia presented this report. They stated that malformations of the esophagus were very rare, even more so than was supposed. Sixty-three cases of the various forms of malformations had been collected by Mackenzie. These were classified as follows: (1) Complete absence of the esophagus; only seven such cases were reported in the literature. (2) Partial or complete doubling of the esophagus; this condition was extremely rare, only two cases being on record. (3) Direct esophageal fistula without other lesion of the esophagus; seven or eight such cases had been reported. (4) Stenosis. This condition might be due to such causes as (*a*) mucous fold; (*b*) malformation of the tube producing a stenosis. These patients might live for many years. (5) Congenital dilatation. This was usually accompanied by dilatation of the end of the stomach. (6) Obliteration of the esophagus without fistula. About eleven of these had been described in the literature. Phillips had reported two cases in the *Archives of Pediatrics*. (7) Partial obliteration of the esophagus with a tracheoesophageal fistula; in Mackenzie's records forty-three of his cases were of this nature. Hoppe had tabulated fifty-nine such cases. The author collected ten or eleven such cases from the literature. They concluded that fistula was nearly always near the upper extremity or the lower fragment. That while the lower extremity was usually of normal size the upper fragment was usually dilated, but tapered gradually as the fistula ran upward. Nearly all cases opened into the trachea. Three cases had been reported where the fistula entered the bronchus. They reported a case (with the typical history) which ended fatally, and the usual conditions were found at autopsy. The pathology of this condition was quite obscure. All treatments gave discouraging results; the children invariably died. A gastrostomy was the only operation that held out any promise of relief.

Spasmodic Stricture of the Esophagus in an Infant of Four Months.—Dr. Samuel S. Adams of Washington reported this case. The child was well nourished for one of its age. When it attempted to swallow something took place which prevented it from swallowing for from sixteen

to twenty-four hours. Any attempts at swallowing caused regurgitation. Upon giving the child some water there occurred a series of attempts at vomiting; finally the water was ejected and a quantity of mucus as well. The case was diagnosed immediately as one of obstruction of the esophagus. The child had swallowed well enough up to the age of three months. The patient was taken to the hospital, where an attempt was made to pass a lavage tube. This failed, and finally a small sound was passed, and this was followed by a feeding tube. In this way the child was fed for some time and gained in weight. The parents took the child, and the attacks continued for fourteen months, though Dr. Adams said he did not see the child. Then the attacks occurred every three or four days for some time. Very recently the child was brought to the hospital, where a physician passed a bougie. On the following morning on passing the sound an obstruction was met with. A false passage had been made. The child developed pneumonia and died. At autopsy there was found a rupture of the diverticulum and signs of posterior pneumonia. The obstruction to the esophagus proved to be a broken down tuberculous gland which had enlarged and compressed the esophagus. He was told that the pathologist was not certain whether the diverticulum was caused by the surgeon or was necrotic. Below this obstruction were two diverticula, one of which would easily admit a pen. The outer one yielded to slight pressure and ruptured.

Dr. Augustus Caillé of New York reported a similar case in a lad of ten years, who had had spasmodic stricture for five years. The condition came on gradually and was purely spasmodic. The boy had had hydrocephalus in infancy, and he doubted whether he would ever get well, as he thought the irritation was of central origin. He warned in regard to the use of the esophagoscope or sound in making examinations. He had recently learned of an instance where the instrument was run into the pleural cavity, in consequence of which a pneumothorax developed and death resulted.

Dr. C. B. Putnam of Boston reported a case, a child of three years, who could not swallow anything and who died after a few days. A condition similar to that described by the reader of the paper was found. The esophagus had a blind ending, the lower portion opening into the trachea.

Dr. Thomas Morgan Rotch of Boston said that an important point in regard to differential diagnosis had been opened up. Some cases of constriction of the esophagus simulated pyloric stenosis. These conditions were almost identical so far as rational signs were concerned. The lower part of the esophagus had a thinner wall in these cases, and this was the reason there was danger of perforating the wall. He had made a careful autopsy in one case where there was congenital stenosis just at the entrance to the stomach and a ballooning of the esophagus from stretching just above. The least mechanical interference before death would have ruptured it. These cases also simulated closely chronic gastric indigestion, and the greatest care should be taken before employing any other method to determine whether or not they were cases of indigestion.

Dr. A. Jacobi of New York asked the exact site of the constriction in Dr. Griffith's case.

Dr. Griffith replied that it was just above the bifurcation.

Dr. Jacobi said that that was the position that gave so much difficulty in the adult. The cause must be looked for in embryonal conditions. The parts were formed separately, but as a rule found each other and so the tube was formed. This was the seat of predilection for cancer in the adult. The muscular layers in these places were incompletely developed. Such places were found throughout the whole intestinal tract.

Dr. Samuel S. Adams of Washington stated that there was no fluid found outside the esophagus, nor was there anything in the bronchial tubes. He thought the pneumonia was the result of the inhalation of some food that the child had tried to take.

Defect of the Ventricular Septum and Absence of the Pulmonary Artery; Symptoms of Angina Pectoris.—Dr. Alfred Hand, Jr., of Philadelphia, reported this case. A boy of three years was admitted to the hospital on July 10 with the statement that he had severe attacks of dyspnea. His history was negative; he had never had the diseases of childhood. He was a blue baby. His first attack occurred in April, 1907, and he had had one attack daily until admitted to the hospital. He then had two attacks a day. The patient seemed to have some pain with each attack, but nothing in the way of an aura was noticed. The mother claimed that convulsions occurred, but the history did not point that way. After each attack he went to sleep. During attacks the respiration was almost stertorous. The action of the heart was rapid, and the sounds were obscured by the noisy lung sounds. The pupils were semidilated. The attacks were of about an hour's duration. The heart was rapid but regular and had normal sounds. The liver reached 2 c.m. below the ribs, the spleen was not palpable. There was no ankle clonus, Babinski's, and no Kernig's signs. On July 11 the attacks lasted nearly two hours, with a great deal of cyanosis, and the patient was much relaxed. There were no clonic or tonic movements. There was a marked dullness over the upper part of the sternum and a brassy cough. He thought of the possibility of enlarged thymus and gave antitoxin, but without effect. He continued to have the attacks for several days, and then had an attack that resembled angina pectoris in an adult. One-twelfth of a grain of morphine was given, which caused the patient to sleep. Any subsequent attack was aborted by the morphine. The temperature ranged from 98.8° to 107.4°, when the patient died. At autopsy an enlarged thymus gland was found. The heart was found to weigh 115 grams and measured 9.5x7.5x 3 c.m. The pulmonary artery was absent, and there was a defect in the membranous portion of the septum. There was no opening from the right ventricle except into the left ventricle. The ductus arteriosus could not be found in the septum, and there were numerous infarcts in the spleen, liver, and kidneys. Complete obliteration of the pulmonary arteries was found. The absence of heart murmurs was thus explained. The distress complained of must have resulted from the fact that there was more blood in the lungs than normal and less in the general circulation.

Dr. A. Jacobi of New York said that the lungs derived their nutrition from dilated bronchial arteries coming from the aorta, which took the place of the pulmonary artery which was absent or stenosed. He had published such a case in which the patient died at the age of 29 years. He did not think the cases were very rare. There was a late systolic murmur that extended all over the heart. The circulation in these cases simply remained fetal.

A Simple Method of Circumcision in the Newborn.—Dr. W. Reynolds Wilson of Philadelphia said that he had been dissatisfied, and with good reason, with the older methods of performing this operation. They were unsatisfactory because of the incompleteness of the removal of the foreskin in those instances where the latter was adherent to the glands; because sutures were placed irregularly and might have to be tightened to the point of unduly constricting the tissues, and as a result there would be edema which might cause the sutures to cut, because of the length of time required for the operation. In operating, the adhesions of the mucous membrane lining the glands were carefully broken up by sweeping the point of the unopened scissors beneath the foreskin. The scissors could then be introduced beneath the prepuce. The skin was first divided with a division of the mucous membrane to a point corresponding to the division of the skin. The mucous membrane was rolled back to the corona and rendered perfectly free. The redundant fold of skin was

trimmed off with the scissors, as well as the mucous membrane on either side of the incision. This was done carefully while the field of operation was kept free from blood. The redundant roll of skin was removed as far as the distal site of the frenum in order to avoid an edematous flap. A tape of gauze, one-half an inch in width, cut so that the edges frayed, was applied, thus securing a roll of mucous membrane in position behind the corona and compressing the blood-vessels. The tape was about ten inches in length in order to admit of several unwindings. The end of the glans should be left uncovered that there might be no obstruction to the meatus.

Dr. S. C. Cotton of Chicago related the method followed by a Jewish rabbi whom he had seen operate twenty-five years ago, and whose operations were uniformly successful. The method was very much like that just described. He adopted the method at that time, but did not recommend it now as he had formerly done.

Dr. Wilson, in closing, said he thought the use of the knife debatable. He used a pair of surgeon's scissors. He related the case of an infant who disengaged himself from the grasp of the nurse and forcibly drew up his legs, causing him to cut into the femoral artery. He succeeded in getting the proximal end of the artery, but the experience had led him to adopt the more simple method.

Pyelitis Terminating in Suppurative Nephritis.—Dr. J. Park West of Bellaire, Ohio, reported this case. The patient was a child, ten months of age, who was taken ill and died within twenty-four days. The first period of her illness seemed to be lobar pneumonia, the second pyelitis, and the third pyelonephritis. It was supposed that the child had pneumonia until after the crisis the sixth day of her illness. After this her temperature went up to 103° without symptoms on the part of other organs. There had been no evidence of vulvovaginitis. On the first day after the crisis a slightly acid urine was noticed containing a number of small cells and epithelial cells. On the following day the urine was like milk and water, and for the eight days following it was clear milk color. Three specimens obtained gave a specific gravity of 1014, 1012, and 1014; they always contained pus, albumin, and abundance of epithelial cells and some blood cells. At times the secretion was scanty and at times free. After the second day of this period the temperature went down gradually. There were no chills nor sweats. There was marked soreness over the body and at times over the left kidney. On the third day there was swelling of the face, hands, feet, and later of the arms which pitted on pressure over the tibia. On the sixteenth day of her illness there suddenly appeared symptoms of severe gastrointestinal disturbance and uremia, which continued until her death eight days later. The urine remained milk-like in color, but did not look so clean. Postmortem the pelvis of the kidney was found to be thin and rough. There were small spots of distended capillaries on the surface. It was a remarkable case of suppurative nephritis. The capsule was invaded, but the blood-vessels in general had a normal appearance. There were bacteria scattered throughout the tissues, but none in the blood-vessels. The bacilli were larger than typhoid bacilli. The tubules were distended with large quantities of lecucocytes and desquamated cells. There were no distinct abscesses. The glomeruli were fairly well preserved. Some of the tubules showed an extreme fatty degeneration of the epithelium. There was considerable débris in the tubules of the medulla, consisting of cells and leucocytes. The fact that there were no changes in the glomeruli and that bacteria were present in the tubules and not in the blood-vessels argued in favor of an ascending rather than a hematogenous infection.

Dr. Isaac A. Abt of Chicago thought it best to cystoscope the bladder and to learn something of the bladder walls and the orifices of the ureters, especially in female children.

Dr. Jacobi of New York asked if gonococci were found.

Dr. West replied that no examination had been made, as there was no history of vulvovaginitis.

Dr. Jacobi said the pyelitis and vulvovaginitis belonged together. He asked if the uterus had been examined.

Dr. West replied that it had not.

Dr. Jacobi said that vulvovaginitis might exist for weeks and months without being detected, as the process was very frequently limited for the time to the uterus, where the gonococci were stored away. This was why cases broke out again after we thought we had cured them.

Dr. Charles G. Kerley of New York said he had been called upon to perform an autopsy upon a case which was supposed to have died from malaria. He found extensive cystitis and multiple nephritic abscesses.

A Case of Apparently Tuberculous Meningitis.—Dr. C. W. Buckingham of Boston reported this case. A boy, seventeen months of age, had malaise for a week or two and cephalic cries. On April 10 a physician was called because of some shuffling in the walk. Vomiting and convulsions followed within the next four days. There was strabismus and dilatation of the pupils, the right more dilated than the left. The knee jerks were unequal and Kernig's sign marked. Babinski's sign was present, and there was no retraction of the head. A lumbar puncture was made and 10 or 12 c.c. of fluid removed, which ran under considerable pressure. The pathological report showed a clear colorless fluid, without sediment. The lower parts were smeared on slides and stained by Wright's method. Eighty-nine cells were found, all but three of which were lymphoid. The diagnosis was made of chronic inflammatory tuberculous meningitis. The pressure symptoms were relieved and the child seemed to recover. This seemed to be one of the few cases of cerebrospinal meningitis where there were prodromal symptoms. The cerebrospinal fluid also contained an excess of mononuclear cells.

Election of Officers.—*President,* Dr. C. B. Putnam of Boston; *First Vice-President,* Dr. Isaac A. Abt of Chicago; *Second Vice-President,* Dr. Thomas S. Southworth of New York; *Secretary,* Dr. Samuel S. Adams of Washington, D. C.; *Treasurer,* Dr. J. Park West of Bellaire, Ohio; *Member of Council,* Dr. Alfred Hand, Jr., of Philadelphia; *Recorder and Editor,* Dr. L. E. LaFétra of New York. Next place of meeting, Lenox, Mass.

An Epidemic of Poliomyelitis Anterior Acuta.—Dr. Henry Koplik of New York read this paper. He said that the epidemic of poliomyelitis that had been engaging the attention of the profession in New York City and vicinity had been extensive; the State Board of Health had registered over 1,200 cases, and it was believed that there were many cases which were not reported. The disease was widely distributed, invading fashionable quarters as well as the poorer localities. There seemed to be nothing unusual in the weather, the atmosphere, the conditions of cleanliness, or the milk and water supply. The epidemic resembled the one that occurred in Horwitz in Sweden. Children of all ages were affected and a few adults. The disease as it manifested itself was not just what was understood by poliomyelitis anterior. Many cases resembled meningitis, but in some things they did not. For instance, a child in apparent health would go into a state of unconsciousness and would develop paralysis of all the extremities. This would be followed by sopor and symptoms referable to the bulb or medulla. There would be difficulty in breathing and in swallowing, with increased coma and paralysis, ending in death from respiratory failure and paralysis. In some cases the abdominal muscles and those of the back and four extremities were paralyzed. In other cases the child would awaken from sleep with acute pain referable in many instances to the joints. Gradually paralysis of one or more of the extremities would develop. There might occur a mild febrile disturbance. After lasting three or four weeks the pain would subside and leave paralysis of one or more of the extremities. The cases that recovered seemed to be merely

cases of neuritis. In a third class of cases the patient would go to bed perfectly well and awaken with paralysis of one or two of the extremities. Perhaps there would be a paralysis of a small group of muscles in the forearm, leg, thigh, or face. Many cases of poliomyelitis anterior began with disturbances of the stomach, a slight febrile attack, and paralysis. There were, therefore, three distinct classes, the cerebral, the neurotic, and the classical. It seemed that all the victims suffered from the same infectious agent. The findings at autopsy in the cerebral cases were identical with those described by Harvey. In many cases nothing was found but a polynuclear cytosis. In the cerebral cases the sensorium was clear when the patients were conscious. The neurotic cases were peculiar in having the pains in the joints and because of hyperesthesia. They were perfectly helpless, and yet their recovery was complete, and it was concluded that there was no affection of the cord, but an affection of the nerve trunks. In this epidemic where the paralysis was permanent the atrophy of the muscles was very rapid. The reaction of degeneration would occur six weeks after the onset of the disease. Some cases recovered completely, some could walk, but the upper extremities remained paralyzed, and some made recoveries with contractures. At the hospital for deformities there were some cases whose only evidence of the disease was facial paralysis and facial atrophy. Some cases gave a history of intestinal disturbances. There was also a set of cases in which there was a tonsilar infection. The nomenclature of the disease would have to be revised. In regard to the treatment he said that hot baths with massage were of value. Electricity sometimes aggravated the symptoms, especially where there was pain along the nerve trunks. In cases of complete paralysis he had found intramuscular injections of strychnine valuable. Cupping along the spine had been tried. The principle aimed at had been to keep up the tone of the muscles that were paralyzed and to wait for recovery.

Early Symptoms of the Recent Epidemic of Poliomyelitis.—Dr. L. E. LaFétra of New York presented this paper. He said that the recent epidemic had furnished the opportunity of seeing many cases of poliomyelitis in which the symptoms presented were not those that occurred in the ordinary conception of this affection. From 63 cases the following suggestive histories were obtained. In 25 cases vomiting occurred; in 14 constipation was present; in 17, diarrhea; in 6, cough, tonsillitis, and sore throat; in 52 cases there was fever. This symptom was probably present in all cases. It generally lasted from two to three days. Restlessness and irritability occurred in 37 cases, delirium in 2 cases, and convulsions in 4 cases. Rigidity of the neck occurred in 11 cases. Babinski's sign in 3 cases at the Babies' Hospital; in 10 cases atrophy was present; in 4 stupor; in 10 headache, and in 3 photophobia. In 32 cases there was pain and tenderness in the affected limb. In 58 cases the paralysis was flaccid and in 5 spastic. The paralysis came on early in the course of the disease. In 1 case opisthotonos existed for five days, and in another for ten. In 1 case there was general anesthesia. In two cases there was unilateral paralysis of the abdominal obliques. Lumbar puncture was done in 14 cases, and from 15 to 70 c.c. of fluid removed. In every instance the fluid was clear. In only 2 cases were cells and mononuclears found. It was exceedingly difficult to diagnose this disease in the beginning of the epidemic. It was especially confusing when acute meningitis was attended with pronounced irritative symptoms.

Dr. L. Emmett Holt of New York did not agree with Dr. Koplik that the disease was limited to New York City. He had been struck by the groups of cases occurring together. These seemed to show that there was probably a mild degree of contagiousness in this form of the disease. He thought they would have to admit that it belonged to the category of acute infectious diseases of the central nervous system.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners, Mississippi.

Examination, May, 1908.

ANATOMY.

1. Give origin, insertion, and nerve supply of: (*a*) tensor fascia lata, (*b*) deltoideus, (*c*) scalenus anticus, (*d*) latissimus dorsi.
2. What are (*a*) neurones, (*b*) neuroglia, (*c*) ganglia?
3. Name the accessory organs of nutrition, and give anatomy of the largest. (Ductless glands.)
4. Describe the celiac axis and give its branches.
5. Describe (*a*) the inferior longitudinal sinus, (*b*) torcular Herophili.
6. Describe, give contents and relations of Scarpa's Triangle.
7. Describe the fourth cervical vertebra, and distinguish it from the fourth dorsal.
8. What structures would be severed in an amputation at the lower third of the arm?

PHYSIOLOGY.

1. Define katabolism, metabolism and anabolism.
2. What are the functions of the red and white blood corpuscles, respectively, and what are the functions of the blood as a whole?
3. Describe the heart cycle, and locate the various valvular sounds, explaining the cause of each.
4. What position should be maintained during the inhalation of chloroform, and why?
5. What change in the density of the blood attends severe hemorrhage, and how is the change accounted for?
6. Where and how are the starches digested? Where and how are the proteids digested? Where and how are the fats digested?
7. What are the chief stimulants to respiration, and what are the changes taking place in the blood and air as they pass through the lungs?
8. Is the specific gravity of the urine higher or lower in cold weather, and why?

CHEMISTRY.

1. Define molecules, and atoms.
2. Define acids, bases, and salts.
3. Describe a reliable test for albumin in the urine, also test for sugar.
4. Describe a reliable test for arsenic; give antidote for arsenic.
5. What is osmosis?
6. What is the difference between a chemical and a physiological antidote?
7. What is the difference between fermentation and putrefaction?
8. Define ptomain poisoning.

MATERIA MEDICA.

1. What would guide you in the selection of ether or chloroform as a general anesthetic?
2. What is the physiological effect of belladonna? Name its alkaloids and dose; explain why atropine is frequently given with sulph. morphia.
3. What is the physiological effect of calomel? The indications and contra indications for giving calomel, and its dose? What are the advantages of combining calomel with sodium bicarbonate, and with pulv. opium?
4. What is Epsom salts, its dose, physiological action, and indications for its use?
5. In what form, size of dose, and disease is iodine usually administered, and how would you prevent iodism?
6. Name the alkaloids of nux vomica, and their dose; what is the effect of strychnia in 1-20 grain doses by mouth, on the circulation, respiration and intestines?
7. What are the general conditions indicating the use of opium? How would you differentiate a case of opium from alcohol poisoning?
8. Describe hypodermocleisis and intravenous injection. Give formula of solution to be used, and state when indicated.

SURGERY.

1. What are the signals of danger in general anesthesia?
2. Give briefly the preparation of patient and surgeon for an abdominal operation.
3. Define surgical shock, and give treatment.
4. Give treatment of a compound fracture of the femur.
5. Describe Bassini's operation for the radical cure of inguinal hernia.
6. Give symptoms and treatment of acute intestinal obstruction.

7. Describe intubation and tracheotomy, and state when each would be indicated.
8. How would you treat a case of acute appendicitis?

OBSTETRICS.

1. How would you determine before labor the presentation and position of the fetus, without a vaginal examination?
2. How would you prepare your patient for delivery, and yourself for attendance in a case of labor?
3. What are the uses of the liquor amnii during pregnancy and labor?
4. Differentiate puerperal sepsis from malarial infection.
5. Name at least six of the most common conditions calling for the use of the forceps.
6. Name three important forms of hemorrhage met with in obstetrical practice, and give treatment of each.
7. How, and how long, would you treat a babe apparently dead when born?
8. Into what stages is labor divided, and when does each stage begin and end?

PATHOLOGY.

1. Define, and mention three most prominent causes of icterus.
2. Mention the pathological condition that distinguishes measles from scarlatina.
3. What is the pathology of acute lobar pneumonia, and how does it differ from broncho-pneumonia?
4. Describe the pathological condition of a case of chronic osteo-myelitis.
5. Describe pathologically a case of salpingitis, and usual cause.
6. What parts are usually affected with diphtheria? How, and by what bacillus?
7. Define embolism, and give five causes.
8. What is the pathology of spina bifida, and where does it most frequently occur?

HYGIENE.

1. What impurities are given off by lighting by illuminating gases and oils, and how best effect their removal?
2. What disease stands forth pre-eminently as a true soil disease, and what are the principal measures of prophylaxis?
3. What relation in area should the windows of a school room bear to the floor space, so as to admit a standard amount of air and light?
4. Name five principal methods of heating residences in Mississippi.
5. State the most satisfactory manner of disposing of the garbage of the towns and cities of our State.
6. Divide disinfectants into their component classes, and give examples of each.
7. What epidemic diseases that we know with certainty can be carried through the introduction of water into the stomach, and state the way they may be prevented.
8. How many cubic feet of air per capita are necessary for each individual adult, or how many people may be put in a room 40x20x15 feet without danger of contamination or vitiating the air?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS, MISSISSIPPI.

Examination, May, 1908.

ANATOMY.

6. Scarpa's triangle is a triangular area or depression situated just below the fold of the groin. It is bounded *above* by Poupart's ligament, *externally* by the Sartorius, and *internally* by the inner margin of the Adductor longus; its *apex* is formed by the junction of the Adductor longus and Sartorius. The *floor* is formed, from without inward, by the Iliacus, Psoas, Pectineus, Adductor brevis, and Adductor longus. *Contents:* The femoral vessels pass from about the center of the base to the apex, the artery being on the outer side of the vein; the artery gives off the superficial and profunda branches, and the vein receives the deep femoral and internal saphenous; the anterior crural nerve lies to the outer side of the femoral artery; the external cutaneous nerve is still further external, lying in the outer corner of the space; just to the outer side of the femoral artery, and in the sheath with it, is the crural branch of the genitocrural nerve. At the apex, the vein (which at the base was internal to the artery) lies behind the artery. The triangle also contains fat and lymphatics.

7. Differences between the fourth cervical vertebra and the fourth dorsal vertebra: *The fourth cervical vertebra* has a small, transversely elongated body, with no facets; the laminæ are long and sender; the spinous process is short, nearly horizontal, and bifid; the transverse processes are short and contain a foramen for the vertebral artery; the superior articular process is directed upward and slightly backward; the inferior articular process is directed downward and slightly forward; the spinal foramen is large and triangular.

The fourth dorsal vertebra has a heart-shaped body with a facet on each side for articulation with a rib; the laminæ are broad and deep; the spinous process is long and points downward; the transverse processes are long, articulate with the tubercle of a rib, and do not contain a foramen; the superior articular process is directed backward and slightly outward; the inferior articular process is directed forward and slightly inward; the spinal foramen is smaller and circular.

8. In amputation at the lower third of the arm, the following structures would be severed: Skin, fascia, biceps, brachialis anticus, triceps and supinator longus muscles; brachial, inferior profunda and a branch of superior profunda arteries; veins, brachial, basilic, cephalic, superior and inferior profunda; nerves, median, ulnar, musculospiral, musculocutaneous, and internal cutaneous; bone, the humerus.

PHYSIOLOGY.

1. *Metabolism* is the entire series of changes that occur in a cell or organism during the processes of nutrition. It is of two kinds: (1) Assimilative, or constructive (anabolism), and (2) destructive (katabolism).

2. The *red corpuscles* supply the tissues with hemoglobin; the *white corpuscles* serve as a protection to the body from the incursions of pathogenic microorganisms, they take some part in the process of the coagulation of the blood, they aid in the absorption of fats and peptones from the intestine, and they help to maintain the proper proteid content of the blood plasma.

The *functions of the blood as a whole*, are: To distribute nourishment, oxygen, and the internal secretions to the tissues of the body; to remove carbon dioxide and other waste matters from the tissues so that they may be excreted by the lungs, kidneys, and skin; to regulate the body temperature.

3. The *cardiac cycle* includes all the changes which occur between the commencement of one heart-beat and the commencement of the next; it consists of the alternate contractions (or systole) and relaxations (or diastole) of the auricles and ventricles of the heart. The contraction of the two auricles takes place simultaneously, and is followed by the simultaneous contraction of the two ventricles; then follows a period during which the whole heart is in a state of diastole. The cycle then begins again with the auricular systole.

There are two normal heart sounds which follow in quick succession, and are succeeded by a pause. The first, or systolic, sound is dull and somewhat prolonged; the second, or diastolic, sound is sharper and shorter. The sounds may be expressed by the syllables *lubb—dup*.

The first sound is heard best at the apex beat in the fifth left intercostal space; the second sound is heard best over the second right costal cartilage.

The *causes* producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) the vibration and closure of the auriculo-ventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall.

The *second* sound is caused by the vibration due to the closure of the semilunar valves.

4. During the inhalation of chloroform the patient should be in the dorsal position, with the neck not too much extended. This position is comfortable for the patient, is less likely to interfere with the expansion of the chest, is not likely to prejudicially influence the respiration and circulation, and the force of gravity tends to keep the vital centers supplies with blood.

5. According to Michael Foster, "hemorrhage lowers the specific gravity of the blood, but the normal or nearly the normal is very quickly regained. The interpretation of the effects of hemorrhage is not clear. We may suppose that the lost volume of blood is in the first instance replaced by plasma only. Though we know that hemorrhage stimulates the production of new red corpuscles, it is difficult to believe that these can make their appearance in sufficient numbers to account for the regained density, seeing that this may occur in less than half an hour. It looks as if the system got rid of the water of the extra plasma, and regained its density by acquiring a smaller volume." (Allbutt's *System of Medicine.*)

6. *Starches* are digested in the small intestine, by the action of the amylopsin of the pancreatic juice; and also to

a very small extent in the mouth, by the action of the ptyalin of the saliva.

Proteids are digested in the stomach, by the action of the pepsin of the gastric juice; and also in the small intestine, by the action of the trypsin of the pancreatic juice.

Fats are digested in the small intestine, by the action of the steapsin of the pancreatic juice; the bile also assists in the emulsification of fats.

7. The chief stimulants to respiration, are: diminution of the amount of oxygen in the blood, increase of the proportion of carbon dioxide in the blood, constriction of the bronchial muscles, weakening of the heart, pain, convulsions, certain drugs (as strychnine, ammonia).

In the blood the changes take place in the capillaries of the lungs, and are: (1) the giving up of the CO_2 by the venous blood, (2) the absorption of oxygen during inspiration, (3) the blood is cooled, and (4) it also loses a small amount of watery vapor.

The changes produced in the *air* by respiration are:

	Inspired Air.	Expired Air.
Oxygen	21 per cent.	16.6 per cent.
Nitrogen	79 per cent.	79 per cent.
Carbon dioxide....	0.04 per cent.	4.4 per cent.
Other gases	Rare.	Often present.
Watery vapor	Variable.	Saturated.
Temperature	Variable.	That of body.
Volume	Varies.	Diminished.
Bacteria	Always present.	None.
Dust	Always present.	None.

8. The specific gracity of the urine is lower in cold weather, because more urine is voided, owing to the lesser excretion of sweat.

CHEMISTRY.

1. *A molecule* is the smallest quantity of any substance (element or compound) that can exist in a free state.

An atom is the smallest quantity of an element that can enter into chemical action.

2. An *acid* is a compound of an electro-negative element or radical with hydrogen, part or all of which hydrogen it can part with in exchange for an electro-positive element, without the formation of a base.

A *base* is a ternary compound capable of entering into double decomposition with an acid to produce a salt and water.

A *salt* is a substance formed by the substitution of an electro-positive element for part or all of the replaceable hydrogen of an acid.

3. *A reliable test for albumin in the urine:* The urine must be perfectly clear. If not, it is to be filtered, and if this does not render it transparent it is to be treated with a few drops of magnesia mixture, and again filtered. The reaction is then observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral, or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3.

Test for sugar: The urine should first be tested for albumin. If this be present, it should be removed by heating the urine to near the boiling point, and filtering from the coagulum.

Fehling's test: Place in a test-tube a few c.c. of the liquid prepared as stated below, and boil; no reddish tinge should be observable, even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of *traces* of glucose, only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out.

[The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystalized $CuSO_4$, dissolved in water to 500 c.c.; and solution II of 130 gms. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

4. *A reliable test for arsenic:* Reinsch's test is as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put it into a clean dry glass tube, open at both ends, and apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

The *antidote for arsenic* is freshly prepared ferric hydroxide, $Fe_2O_6H_6$. The two following solutions should be mixed and administered:

(1) ℞ Liquoris ferri tersulphatis..... ℥ij
Aquæ destillatæ ..... ℥vj. M.

(2) ℞ Magnesiæ ..... ʒiij
Aquæ destillatæ ..... ℥viij. M.

5. If two liquids be separated from each other by a membrane, each will pass through the membrane into the other. This phenomenon is called *osmosis.*

6. *Chemical antidotes* act as such by uniting chemically with the poison and thus converting it into a harmless or insoluble compound.

Physiological antidotes act as such by combating the physiological action of the poison.

7. Both fermentation and putrefaction are forms of decomposition of organic matter under certain favorable conditions. When the organic matter is composed of carbon, hydrogen, and oxygen only, the process is called *fermentation;* when nitrogen and sulphur are also present, *putrefaction* is said to occur.

8. *Ptomaine poisoning* is poisoning by the putrefaction products of dead animal tissues and fluids.

MATERIA MEDICA.

1. As a general rule, ether would be the anesthetic of choice. But chloroform may be used: (1) in hot climates; (2) when large numbers of persons have to be rapidly anesthetized; (3) in brain surgery; (4) in labor; (5) in patients who are known to take ether badly; and (6) in the conditions mentioned below, in which ether is contraindicated.

The following contraindications for ether and chloroform are from Hare's *Practical Therapeutics:* "*Ether* should not be used by inhalation in bronchitis or acute nephritis, because of its irritant properties: in peritonitis or gastritis, because it is apt to induce vomiting; in aneurysm or in the presence of marked vascular atheroma, because it may rupture a blood-vessel by raising arterial pressure; nor in diabetes, lest it produce diabetic coma; and if anemia is present and an examination of the blood shows that the hemoglobin is below 50 per cent., the use of the drug should be avoided if possible.

"*Chloroform* is not to be used in cases of fatty heart or dilatation of the heart, in those with a known idiosyncrasy, nor in the so-called lymphatic persons with overgrowth of lymphoid tissues, as, for example, adenoids. In the latter case it is particularly apt to cause sudden death. In valvular disease of the heart chloroform may be used with caution, although ether is preferable. Given a case of valvular disease that must be subjected to operation, the chances are bettered with an anesthetic than without it, as the pain and mental shock are worse for the heart than is the anesthetic."

2. Belladonna. *Physiological effects:* Anodyne, mydriatic, inhibits secretions, depressant of terminations of nerves, accelerates the heart beat, causes rise in blood pressure, but toxic doses cause the blood pressure to fall, stimulates the respiratory center, but large doses depress the same; it may cause vertigo, restlessness, excitement, delirium, or mania.

Alkaloid.—Atropine: *Dose* of the sulphate of atropine is gr. 1/250 to 1/40.

Atropine is often combined with morphine when the latter is used, for the following reasons: (1) To prevent nausea and insomnia; (2) to intensify the effect of the morphine, and so a smaller dose may suffice; (3) to neutralize the effect on the pupils.

5. Iodine is usually administered in the tertiary stage of syphilis; in the *form* of potassium iodide; *dose*, gr.v to lx in solution. The addition of ♏v of the tincture of belladonna to each dose of the iodide is said to prevent iodism.

6. Nux Vomica.—*Alkaloids:* Strychnine and Brucine. *Dose:* Strychnine, gr. 1/64 to 1/16; strychnine sulphate, gr. 1/64 to 1/16; strychnine nitrate, gr. 1/64 to 1/16; brucine, gr. 1/32 to 1/16.

The effect of strychnine on the *circulation,* is to increase the rate and force of the pulse beat; on the *respiration,* is to increase the rate and also the respiratory capacity; on the *intestines,* is to increase peristalsis.

7. In *opium poisoning:* The pupils are contracted, the respiration is slow and full, the skin warmer than in alcohol poisoning, the face suffused, and the pulse slow and full.

In *alcohol poisoning:* The pupils are not contracted, the respiration approaches the normal, the skin is cool and sometimes moist, the face may be pallid, and the pulse is rapid.

SURGERY.

1. *The signals of danger in general anesthesia* are: Irregular, shallow, and slow respiration, preceded by quickened respirations; irregularity of the pulse, accompanied by a weakened pulse; dilatation of the pupils (unless the patient is coming out of the influence of the anesthetic); lividity or extreme pallor of the face.

3. *Shock* is the name given to a sudden and general depression of the vital powers, due to some strong stimulation (such as injury or emotion) acting on the vital centers in the medulla, and producing vasomotor paralysis.

Treatment of shock: Place the patient in the recumbent position, with the head low, apply warmth to the body, administer a stimulant, and give a hot saline infusion; morphine, hypodermatically, may be necessary for the relief of pain.

8. *Treatment of acute appendicitis:* The patient should be kept in bed; no food is to be given for the first twenty four hours; after this, fluid and jellies may be given; cooling drinks may be allowed in moderation; the pain can be relieved by hot or cold applications on the right iliac region, or morphine may be given if necessary; an enema of olive oil or glycerine may be given to empty the bowels (if loaded).

The indications for appendectomy vary according to the views of the surgeon. Some maintain that every case of appendicitis should be operated on as soon as the diagnosis is made. Others would operate only in case of rupture, or when suppuration occurs, or in cases which do not improve in a week or so, or in cases which are steadily getting worse. Probably all would agree in taking out every appendix that has undergone more than one mild attack.

OBSTETRICS.

3. *Uses of the liquor amnii.*—(*a*) *During pregnancy:* (1) As a protection to the fetus against pressure and shocks from without. (2) As a protection to the uterus from excessive fetal movements. (3) It distends the uterus, and thus allows for the growth and movements of the fetus. (4) It receives the excretions of the fetus. (5) It surrounds the fetus with a medium of equable temperature, and serves to prevent loss of heat. (6) It prevents the formation of adhesions between the fetus and the walls of the amniotic sac. (7) It has been supposed, by some, to afford some slight nutrition to the fetus.

(*b*) *During labor:* It acts as a fluid wedge, and dilates the os uteri and the cervix; it also slightly lubricates the parts.

4. The following table (from Dorland's *Obstetrics*) differentiates the two conditions; but a careful blood examination, by revealing the presence or absence of the *plasmodium malariæ*, will render the diagnosis certain.

PUERPERAL SEPSIS.	MALARIAL INFECTION.
The chills are irregular in their appearance and are associated with marked alterations in the temperature rate.	The chills occur at regular intervals, and are followed by the usual elevation of temperature and then a sweat.
The constitutional disturbance is profound.	The constitutional depression is moderate, and quite out of proportion to the severity of the paroxysm.
The pulse rate is exceedingly rapid and ominous.	The pulse rate is in proportion to the amount of febrile reaction.
There will be associated uterine subinvolution and tenderness, and probably alteration in the lochia.	There will not be noted any peculiar local pelvic manifestations.
The patient's condition steadily grows worse without appropriate treatment.	Within a few hours there will occur a marked amelioration of the symptoms.

5. Six of the most common conditions calling for the use of the forceps: (1) Uterine inertia; (2) prolapsed funis, with threatened death of the fetus; (3) occipito-posterior positions; (4) eclampsia; (5) hemorrhage from premature detachment of placenta; (6) small amount of pelvic contraction.

8. Labor is divided into three stages: The *first stage* begins with the commencement of labor, and ends with the complete dilatation of the os uteri. The *second stage* begins with the complete dilatation of the os uteri, and ends with the birth of the child. The *third stage* immediately follows the second, and ends with the expulsion of the placenta and the beginning contraction of the uterus.

PATHOLOGY.

1. *Icterus* is the condition in which the tissues of the body are discolored by bile pigment.

Three causes: (1) Obstruction of the bile duct; (2) various poisons in the blood; (3) excessive secretion of bile.

2. In *scarlatina* the serous membranes are more often involved than the mucous membranes, and acute nephritis is a common complication.

In *measles* the mucous membranes are involved, nephritis is not a complication.

Of course the eruption differs: In *scarlet fever* the eruption is brighter, is on a red background, punctiform, and is more uniform; the temperature is higher, the pulse quicker; the tongue is of the "strawberry" type, the lymphatics in the neck may be swollen, and there is sore throat.

In *measles* the eruption is darker, less uniform, more shotty; the temperature is lower, pulse slower, the tongue is not of the "strawberry" type; coryza, coughing, and sneezing may be present.

3.

ACUTE LOBAR PNEUMONIA.	BRONCHOPNEUMONIA.
Generally a primary disease.	Generally secondary (to bronchitis or an infectious disease).
Age has little influence.	Generally found in very young or very old.
Sudden onset.	Gradual onset.
Fever is high and regular.	Fever is not so high, and is irregular.
Ends by crisis between sixth and tenth day.	Ends by lysis, at no particular date.
Generally only one lung affected.	Generally both lungs affected.
The physical signs are distinct; and there is a large area of consolidation.	Physical signs indistinct; and the evidences of consolidation are indefinite.
Sputum is rusty.	Sputum is rather streaked with blood.

6. The parts usually affected with the diphtheritic membrane are: Larynx, tonsils, epiglottis, pharynx, trachea, mucous membrane of the nares, bronchi, soft palate, uvula, and esophagus. The bacillus is the Klebs-Loeffler bacillus.

7. *Embolism* is the plugging of a blood-vessel by a foreign body. *Five causes:* (1) Vegetations from the cardiac valves; (2) detached thrombi; (3) oil globules; (4) parasites; (5) fragments of tumors.

8. Spina bifida is a condition in which there is a cleft in part of the posterior wall of the spinal column; it is due to imperfect development. Through this cleft there may protrude the spinal meninges and cerebrospinal fluid (meningocele); or it may contain in addition some of the cord and nerves (meningomyelocele); or there may be great distention of the central canal, the sac-wall being formed of the thinned cord (syringomyelocele).

It most frequently occurs in the lumbar or dorsal region.

HYGIENE.

2. A true soil disease is tetanus. The principal measures of prophylaxis are: To cleanse and keep open all wounds contaminated with the soil; all wounds containing foreign matter, and all Fourth of July wounds; tetanus antitoxin should be used where tetanus is feared.

3. The window area should be about one-eighth to one-sixth of the floor area.

4. Five principal methods of heating residences. Open fires, stoves, gas, steam, and hot water.

6. Disinfectants may be classified as: (1) *Mechanical*, such as scrubbing, shaving, irrigation. (2) *Chemical*, such as bichloride of mercury, carbolic acid, lysol, hydrogen peroxide. (3) *Thermal*, such as *moist heat* (steam, boiling water), *dry heat* (flame, cautery).

7. Epidemic diseases that can be carried through the introduction of water into the stomach are: Typhoid, cholera, and dysentery. To prevent the spread of these diseases: All water for drinking or for washing dishes, etc., and milk should be boiled; no ice should be put *in* water or other drink or food; flies should be kept out of the house; all discharges from the sick persons must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed, and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient, physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over.

8. Three thousand cubic feet per hour is the accepted standard allowance of fresh air for each adult. As the air can be changed (by proper ventilation) three times in an hour, one thousand cubic feet of space is required for each adult. Hence, a room 40 x 20 x 15 feet should accommodate $\frac{40 \times 20 \times 15}{1000} = 12$ persons.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. 5
Arizona*	Ancil Martin, Phoenix	Phoenix	Jan. 4
Arkansas*	F. T. Murphy, Brinkley	Little Rock	Jan. 12

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular state.

Treatment of Chancre.—Erdös advises the following method: If the chancre is of recent date and situated on the free edge of the prepuce or of the labium as the case may be, excision followed by aseptic suture, is to be recommended. If the sore is ulcerated and of long duration, two months, for instance, and if excision is impossible, a few drops of a soluble salt of mercury, such as the benzoate, the biniodide, or the bichloride, may be injected around the chancre. Having washed the parts with a solution of sulphate of copper or nitrate of silver of strength 1 in 50, an ointment should be applied consisting of 1 gram of white precipitate, ½ gram of resorcin, 30 grams of simple ointment, and 10 grams of lanolin. The same ointment can be used for the normal chancre. The internal treatment should consist as much as possible in mercurial injections. If these are not permitted, the ordinary inunction treatment should be followed.—*Lancet.*

Pathogenesis of Psoriasis.—Giuseppe Verrotti, after a careful consideration of the causes, hematology, histology, and urology gives us his conclusions. The most complete theory for the interpretation of the clinical facts of the disease is that of autointoxication. The only other theory that is worthy of discussion is the parasitic theory. It is not possible to admit that a parasite can produce the morphological entity that is called psoriasis. Such a parasite must work on the superficial layers of the epidermis, while psoriasis involves the deeper layers of the skin. The process of psoriasis may be aggravated by the presence of microorganisms which act as exciting causes, just as chemical, thermal and mechanical irritations act in persons that are predisposed to the disease. These agents act upon a soil that is ready for their life by reason of gastro-intestinal or metabolic failure and poisonings, which are necessary to its production. There must be a congenital or acquired perversion of the cellular metabolism underlying the whole process.—*Giornale Internazionale delle Scienze Medicale.*

Contagious Diseases. Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City for the week ending October 17, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	486	138
Diphtheria	311	19
Measles	119	2
Scarlet Fever	109	5
Smallpox	1	—
Varicella	30	
Typhoid Fever	105	23
Whooping Cough	22	5
Cerebrospinal Meningitis	4	7
Malarial Fever	—	—
Totals	1187	199

Immediate Treatment of Osteomyelitis of Adolescents.—M. P. Hardouin sums up the subject of treatment of osteomyelitis in adolescents by saying that such a condition is always infectious and begins in the bone medulla; it should be treated by trephining, rapidly done, and thoroughly accomplished. Treatment to have the best results must be undertaken within the first forty-eight hours. Unfortunately, few cases come to the physician so early. There are rare subperiosteal abscesses that are primary, and which can be treated by simple incision and drainage. The most common ones are secondary to acute osteomyelitis of the epiphysis. These must be thoroughly opened and all dead bone removed at once. The diagnosis is established by the symptoms, acute inception, with high fever, intense pain, increased on palpation and pressure, with enlargement below the knee joint. Rheumatism of a single joint would be rare and less severe. A large incision is made deeply through all muscles and fasciæ down to the front of the tibia, the trephine applied until all diseased bone is removed, all pus removed, the wound cleansed, and drained.—*La Presse Médicale.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending October 16, 1908:

INTESTINAL INFECTION AND IMMUNITY IN TUBERCULOSIS.*

By PROF. A. CALMETTE,

LILLE, FRANCE.

DIRECTOR OF THE PASTEUR INSTITUTE OF LILLE.

Permit me to express, first of all, my gratitude for the great honor which you have bestowed upon me in inviting me to discuss before your illustrious society the present state of our knowledge of the rôle of the digestive tract in tuberculous infection and in immunization against tuberculosis.

For several years this question has been the principal object of my laboratory researches, which I have pursued with the aid of some of my scholars, particularly of C. Guérin. It has engaged the attention in an equal degree of a large number of workers in every country. There are but few of greater interest, as the discussions of our recent congress will bear witness.

I do not pretend that I can cast sufficient light upon this question to warrant us in expecting in the very near future the establishment of a method capable of protecting humanity against the most terrible of the scourges which desolate it. I do wish, however, to make an effort to acquaint you with the principal experimental facts upon which we can build to-day so as better to comprehend the mechanism of the tuberculous infection, and I trust that you may be brought to regard the hopes which have been raised so many times in vain, as at least partly realizable.

It is forty-three years since Villemin announced that tuberculosis is inoculable and contagious, and twenty-six years separate us from the memorable epoch at which Robert Koch, discovering and cultivating his bacillus, made the demonstration of its specificity. Notwithstanding the enormous accumulation of publications in the last quarter of the century, we are still but very imperfectly informed upon the respective importance of the different ways by which the virus of tuberculosis can penetrate into the bodies of man and of susceptible animals. Until lately, the greater number of scientists, clinicians or experimental workers, have considered as an indisputable dogma the respiratory origin of pulmonary tuberculosis, and the celebrated debates which took place at the international conferences at The Hague in 1906 and at Vienna in 1907, and since then in various learned societies, are so fresh in your minds that it would be useless to recall them. It appears, however, that the impression that a final decision had been reached is not correct, and that, as is always the case, the truth lies between two extremes.

If it appears undeniable that in certain probably very rare cases, direct infection of the lung takes place through the respired air, notwithstanding the many and very efficacious natural defenses which line this route, it is also manifest that the path to the pulmonary parenchyma normally followed by the tubercle bacillus is most often through the lymph or blood-vessels, the great portal of entry being the digestive tract.

Experimentation has shown that to effect primary tuberculous infection of the lung by the air, it is necessary to place the animal under pathological conditions, as has been done by Nocard, Flügge, and, more recently, Kuss, in immobilizing the animals so as to oblige them to breathe for a long time an atmosphere charged with infectious particles, liquid or dry. Very fine spray is certainly dangerous, above all for young infants, and it is evident that pneumonia with early caseation and acute pulmonary tuberculosis of infants are almost always of respiratory origin. When a mother or a nurse, the subject of an active pulmonary tuberculosis, coughs or sneezes at a short distance from the lips of an infant breathing through its open mouth or crying in expectation of the breast, contagion by inhalation is all but fatal. But this mode of infection is certainly exceptional for the older child or for the adult.

Infection by dust laden with bacilli is more exceptional still; and the positive results of Cornet, as well as those of Kuss, accomplished by shutting up the immobilized animals in an inclosed space, in an atmosphere of talcum powder or of the débris of vegetable fibers mixed with dried sputum, invalidate in no way the much more numerous negative results described by Baumgarten, Tappeiner, Cadéac and Mallet, and Petersson, and by myself with Vansteenberghe.

Does not, however, the normal asepsis of the respiratory tract attest strongly the protective efficiency of the defensive apparatus of this region, when not affected by preexisting lesions of the nasopharynx, of the larynx, and of the larger bronchi?

The primary lesions of the tracheal and bronchial nodes, which certain authors consider as always related to a respiratory infection, can no longer be invoked as a convincing argument in favor of this view. If it be true that, following the law of Parrot, the nodular lesion should always be accompanied or preceded by one or several pulmonary tubercles, there is nothing to prove that these last must be of aerial origin, since they make their appearance with great frequency in animals artificially infected through the digestive tube. Breton and myself have observed this regularly upon a great number of guinea-pigs which had absorbed through the rectum or been given by an esophageal sound, a small quantity of a fine emulsion of a pure culture of the bacillus of bovine tuberculosis. These animals when killed after four or five weeks very often presented no other lesions than one or two superficial tubercles, as large as the head of a pin, in one of the anterior lobes of the lung, with a coexisting extensive tuberculosis of the peribronchial lymph nodes. An observer who was ignorant of the conditions under which the infection had been experimentally pro-

*Lecture delivered before the Harvey Society, at the New York Academy of Medicine, October 24, 1908.

duced, would undoubtedly have stated that the lesion was due to respiratory infection.

It can then hardly be denied that if primary tuberculosis of the lung or of the tracheobronchial lymph nodes by the direct inhalation of particles carrying bacilli is quite possible in some cases, it is certainly exceptional.

Quite frequent, on the other hand, but also less serious, is infection of the body through the digestive tract.

When I state that tuberculosis is most often contracted through the intestine, I do not wish to be considered as saying that I attribute to the food, and consequently to the milk of tuberculous cows, the essential rôle in the tuberculous infection of man. I am convinced, on the contrary, that the importance of infection through milk has been very largely exaggerated in the last few years. The fact that tuberculosis is so common, both in infants and in adults, in countries where the use of cows' milk as human food is exceptional, for example, in Egypt, India, Indochina, and Japan, shows that the propagation of tuberculosis from man to man is infinitely more common than the infection of man by cattle.

Without doubt the ingestion of the milk of tuberculous cows is dangerous, principally for young children, though even for healthy adults, and much more for those in whom the intestinal mucosa is not intact, when the ingestion of virulent material is frequently repeated. But infinitely greater and more frequent is the danger from human bacilli freshly expelled from the lung of a consumptive, when these bacilli are carried by the sputum to the food or upon the mucous membrane of the mouth by direct or indirect contact of the lips, the hands, soiled objects, etc., or by flies. The tuberculous mother who tastes the dish prepared for her child or who wipes its face with her handkerchief, and the nurse who moistens her breast with her saliva, subject the infant in their care to the danger of tuberculous infection. The child who handles its food after crawling about the floor, and the man who wets his fingers to turn the pages of a book, or to handle type, or who works with tools belonging to a consumptive whose sputum contains the bacilli, may ingest at any moment a number of virulent bacteria; and the risks of contagion are much more serious the more abundant and frequently repeated these ingestions are.

And how can one doubt that the rôle of flies is particularly important and dreadful in the unhealthy tenements where, among the sick persons, children and adults, living side by side in the closest contact, these insects swarm in compact masses alternately upon the sputum and upon the food?

Careful study of the tuberculous infection in animals furnishes abundant clinical proof of the predominance of infection through the digestive tract.

For example, it is known that the flesh-eating animals such as the lion, the tiger, the hyena, and the jackal, when confined in a menagerie and fed upon tuberculous meat, often become infected with tuberculosis, either pulmonary or visceral, whereas these animals never show spontaneous tuberculosis in the wild state. The dog becomes tuberculous when he swallows the sputum of his sick master; the calf, the cat, and the pig contract the disease when they are fed upon milk rich in the bacilli.

Insistence has rightly been laid, in recent times, upon the complete absence of tuberculosis in American pigs fed exclusively upon corn or other vegetable substances which may have been cooked, whereas this disease is extremely common in the pigs of our European farms, above all where the animals are fed upon the unpasteurized waste from dairies.

It is evident that tuberculosis thus developed—most often with primary lesions in the pleura or bronchial lymph modes—in pigs fed upon the milk of tuberculous cows, results from the absorption of the bacilli through the digestive tube. These ingested bacilli are able to penetrate the intestinal wall, and enter into the blood or lymphatic circulation, and are carried about in the body for a greater or less time before they produce the lesions characteristic of the tuberculous infection.

This fact was first demonstrated experimentally by Chauveau, in 1868 to 1872, and then by Villemin, Aufrecht, Gerlach, Klebs, Gunther and Harms, and a number of other observers, among whom one may mention Saint-Cyr, Viseur, Bollinger, Orth, Toussaint, Baumgarten, Rabinovitch, Parrot, Ravenel, Schroeder and Cotton, etc. Nevertheless, certain negative results attract attention, particularly those published by Colin (of Alfort) and by Moeller, which seem to demonstrate that animals can swallow with safety large quantities of tuberculous material. We now know the reason of this. It is because artificial infection through the digestive tract is not invariable unless one takes certain precautions which I have definitely pointed out in studies with C. Guérin. It is necessary to cause absorption of the bacilli in a divided state so that they remain finely emulsified, as they are in the sputum or in milk. Under these conditions a single administration of infectious material is ordinarily sufficient to produce the tuberculous lesions, which in young animals most often remain localized for a longer or shorter time in the mesenteric lymph nodes, but which in adults, on the contrary, appear at once in the lungs.

In studying the mechanism of the absorption of inert dust by the intestinal mucosa, I have been able to establish, with Vansteenberghe, that the same phenomena can be observed. The ingestion of finely powdered lampblack, or, better, of India ink, mixed with the food, produces in the adult guinea-pig the typical lesions of anthracosis of the lung, whereas in the young guinea-pig the colored granules remain for a longer or shorter time in the mesenteric nodes. Sections of the small intestine fixed during digestion allow one to recognize these colored granules surrounded by leucocytes in the chylous vessels of the villi.

In repeating our experiments upon this subject, Sir William Whitla* and Symmers have recently reached the same conclusions; and these workers have described an ingenious procedure which permits them to produce simultaneously tuberculosis and anthracosis of the lung or of the mesenteric nodes. This procedure consists in causing young or old guinea-pigs to swallow an emulsion of tubercle bacilli and India ink in olive oil.

Experimentation upon large animals such as cattle permits the determination with still greater certainty of the path which the tubercle bacilli follow to the lungs, if the animals are sacrificed, as in my experiments with Guérin, at successive intervals from the time of a single ingestion of the infectious material. One can thus convince himself, as has been shown by Chauveau, afterwards by Dobroklowski, that these bacilli penetrate the intestinal mucosa, even when this is entirely intact, and that they generally leave no trace of their passage. They are transported by the polynuclear leucocytes from the chylous vessels of the villi to the nearest mesenteric nodes.

In suckling animals and in young infants, they are frequently retained in the lymphatic organs which

*The Etiology of Pulmonary Tuberculosis. Cavendish Lecture, 1908. *Lancet* or *British Medical Journal*, July 11, 1908.

act as an almost perfect filter for the lymph. Sometimes they are destroyed in the nodes; sometimes they give rise to tuberculous lesions which, developing towards caseation, throw off their microbes into the efferent lymphatic canals, or occasionally into the peritoneum.

In older subjects, in whom the mesenteric nodes—as has been shown by Weigert—are much more permeable, the bacilli, always surrounded by polynuclear leucocytes, are carried with the lymph through the thoracic duct as far as the right ventricle of the heart, and thence forced into the capillaries of the lung. If the leucocytes carrying the bacteria have lost their ameboid movement because of the intoxication resulting from the tuberculin secreted by the bacilli, they are incapable of penetrating the walls of the capillaries by diapedesis, and they then give rise to fine emboli which become the starting point for a corresponding number of tuberculous lesions at the expense of the endothelial vascular walls (the gray granulations of Laennec).

The tuberculous lesions thus formed go on later to calcification or to caseation. In the second case, the tubercles drain into the alveoli or into some lymphatic vessel or vein, more rarely into an artery. They thus bring about a dissemination more or less rapid and more or less grave, of the virus into other parts of the body.

In my researches with Guérin, I have always been able to show the extreme frequency of adenitis of the tracheobronchial glands in young cattle, when the bacilli have penetrated the filter formed by the mesenteric nodes, and have reached the lung. This adenitis is in constant relation with one or several tuberculous subpleural lesions which it is easy to discover.

The digestive origin of these lesions is entirely evident. We have reproduced them many times, and Vallée (of Alfort) has also obtained them, either by feeding calves on milk proved to be from tuberculous cows, or by inoculating the bacilli directly into the mesenteric nodes after laparotomy.

Further, we have observed in some of our animals infected through the digestive tract, primary localizations of tuberculosis in other organs than the mesenteric nodes or the lungs. We have seen these appear under the form of pleurisy, of arthritis, of orchitis, and, in one very remarkable case in a young kid, of iritis. These exceptional localizations occurred only in animals infected by a single administration of small quantities of bacilli. One can suppose that these, because of their small number, had remained for a long time in the circulating blood, carried about by some polynuclear leucocytes, and that they had finally established a tuberculous lesion only in the organ where these leucocytes were when they succumbed.

Whatever interpretation may be accorded to these facts, it remains certain that so-called primary pulmonary tuberculosis and many other forms or localizations of tuberculous infection, manifestly result in a great number of cases from the penetration of the poison through the digestive tract.

Partisans of the theory that infections by inhalation predominate, above all Flügge in Germany and Kuss in France, bring forward the objection that in order to produce tuberculosis experimentally by ingestion, it is necessary to cause the animals to absorb thousands or millions of the bacilli, whereas a few individuals alone suffice to produce tuberculous lesions of the lung when they are inhaled. Those who think thus forget too often that among the millions of ingested bacilli there is only a small number—undoubtedly only a few individuals—which succeed in penetrating the intestinal mucous membrane, and that the greater part of those which break through are subsequently destroyed in the mesenteric nodes. Finally, there are only a few which are carried by the leucocytes as far as the flow of lymph in the thoracic duct or as the capillaries of the lungs. But those bacteria which attain these situations establish the intravascular tuberculous formations so well described by Borrel, and later by Letulle, the slow development of which in successive steps finally gives rise to phthisis.

If so many physicians still persist in believing that man behaves differently from animals in the face of tuberculous infection, it is perhaps because the old ideas on *miasma* still weigh upon our brains. Without doubt, some among us have exaggerated the importance and the frequency of the infection of man by milk, and those who contend to-day that tuberculosis is contracted through the intestine more often than through the respiratory tract, bear the burden of these exaggerations.

We must protest also against this tendency to identify *intestinal origin* with *alimentary origin*. It is very certain that for our species the human patient is—I cannot repeat this with too much emphasis—the principal factor in the dissemination of tuberculosis. But I believe it necessary to declare strongly that while man can exceptionally contract tuberculosis, above all in infancy, by the inhalation of the bacilli, he contracts it much more often by intestinal absorption, repeated frequently for a long time, of some of these same bacilli freshly thrown off by a consumptive.

At the Congress of Veterinary Medicine of Cassel, on September 26, 1903, Von Behring advanced the theory that pulmonary tuberculosis of the adult might well be merely a tardy manifestation of a tuberculous infection contracted in infancy. He laid emphasis, to support this opinion, upon the frequency with which pulmonary lesions are observed in adult cattle, whereas in young cattle the mesenteric lesions are the most frequent.

My experiments with Guérin, and also those of Vallée (of Alfort) have shown the inaccuracy of so absolute a statement. We know to-day that a primary pulmonary tuberculosis can be produced in adult cattle, goats, monkeys, and guinea-pigs, by feeding these animals on infected material once or several times.

Since infection by the digestive tract is so easy, there is reason for astonishment that tuberculosis is not a still more widely spread and deadly disease among live-stock than it is.

Now then, veterinarians and stock breeders have frequently stated that certain animals remain immune, although they have been in contact for years with animals suffering from the disease. More often still it happens that cattle react sharply to tuberculin at the first trial, cease to react a little later, and retain all the appearances of the most perfect health.

Must it then be admitted that in the first subjects the tuberculous poison has not been able to gain a foothold, and that the second are capable of complete recovery after a first attack? Here again, experimentation will enlighten us.

When we compel young calves to swallow, in a single contaminated meal, a small dose of tubercle bacilli of bovine origin, which have been very finely divided in order to facilitate their absorption, we notice that all these animals, without exception, contract tuberculosis. They react, on an average, thirty days later to the tuberculin test; and if we test them again each month following we find that after three, four, or five months, some of them cease to react. On being slaughtered these last present

no tuberculous lesions, and if, having saved them, one attempts to reinfect them a short time after, by making them absorb a fresh dose of poison certainly capable of infecting other calves of the same age, one finds that they remain immune.

These animals then have really recovered from the primary lesions, and they should be considered as vaccinated, at least during a certain time the duration of which is still undecided.

On the other hand, if we administer to calves, not a single time but in several successive feedings, at close intervals, a series of small doses of the bacilli, not only do they never cease to react to the tuberculin, but we find that in them tuberculosis develops very quickly and becomes rapidly fatal.

It is then the animals which are exposed to a series of successive reinfections, so close together that they have not time to recover from the first attack, which become definitely and fatally tuberculous.

We understand from this why, under conditions moderately predisposing to infection, certain subjects resist contagion for a longer or shorter time: it is because they have actually been vaccinated or rendered insusceptible by a previous attack, the lesions of which had time to heal before a new occasion for infection offered.

It is not easy to furnish proof that this state of immunity acquired by a previously successfully resisted attack exists also in man. Prolonged clinical observation of old cases, however, permits us to affirm that it is, at least in many cases, very probable. It appears especially evident in old cases of scrofulous lesions, and since the statements of Marfan in 1886, numerous doctors have described it.

One must inquire whether this is a question of a true immunity, of longer or shorter duration, supported not only by the absence of the reaction to tuberculin—which is not sufficient demonstration—but also by the non-persistence of the virulent bacilli in the different groups of lymph nodes in the body.

The experiments which I have carried out upon this subject with Guérin demonstrate that at the end of the fourth month after the ingestion of the bacillary vaccine, a lymph node is no longer virulent for the guinea-pig. The bacilli have then been absorbed and have completely disappeared.

We have attempted to prove the resistance of animals thus vaccinated through the digestive tract, with reference to an intravenous inoculation so serious as surely to produce in the control subjects the rapid development of an acute miliary tuberculosis with death in four to six weeks. This proof has been accomplished in six cattle, eight and twelve months after the administration of the vaccine. All the vaccinated animals were resistant and preserved the appearance of the most perfect health. But suddenly, about eight months later, one among them, although strict isolation was maintained so that infection from an outside source was impossible manifested the first symptoms of a serious tuberculosis of the udder. All the others were then slaughtered; they did not react to tuberculin, nor did they show any visible tuberculous lesions, but their bronchial and mediastinal lymph nodes still contained living bacilli which were virulent when inoculated into guinea-pigs. The bacilli which had been injected intravenously, then, were not absorbed after eight months, whereas the bacilli which had previously been introduced by the digestive tract were not discoverable at the fourth month. And these bacilli remained latent in the body, not exciting any pathological trouble, up to the day when, the immunity ceasing, they became capable of suddenly producing disorders more or less grave.

From other experiments we are able to state that the cattle already suffering from benign tuberculous lesions and reacting to tuberculin, or that healthy cattle prepared by two or three large intravenous injections of tuberculin, manifest a resistance entirely exceptional to the severe tuberculous infections taking place through the veins. While the new subjects succumbed to the acute miliary tuberculosis in four to six weeks, the animals already tuberculous or prepared as I have above described contracted constantly a chronic form of tuberculosis with a very slow development. They showed, then, a resistance incomparably superior to that of the healthy animals.

One observes the same phenomena in cattle artificially or spontaneously tuberculized through the digestive tract, when one inoculates them later with a culture of tubercle bacilli subcutaneously. Thus Koch had already described in the tuberculous guinea-pig, at the time of his first work upon tuberculin, the formation of an abscess at the point of inoculation, but the neighboring nodes did not become infected, and the abscess healed when it opened on the surface.

Analogous facts are frequently established in clinical work on man. Every one knows that a local tuberculous suppuration occurring in a person with pulmonary tuberculosis, ameliorates the condition of the patient and considerably increases his resistance. Inversely, it is rare that patients in whom pulmonary tuberculosis has had a rapid development have been attacked previously by suppurations of the lymph nodes, or bony or cutaneous tissues, except in the cases where an inopportune surgical operation has provoked an infection of the blood. It is a well known fact that about a quarter of the persons suffering from lupus present the auscultatory signs characteristic of pulmonary tuberculosis, and that these generally develop in them with very great slowness; likewise many lupus patients live to an advanced age.

If one recalls that certain clinicians have pretended to obtain in phthisical patients real amelioration following the subcutaneous inoculation of cultures of virulent bovine tubercle bacilli (F. Klemperer), or of dead bacilli (Maragliano), or of cultures of human tubercle bacilli modified by passage through the body of a cold-blooded animal (crocodile) (Moeller), the experimental facts of which I have just spoken are of a nature to justify such assertions in a certain measure. But such a therapeutic method is certainly to be condemned; and so much the more because we possess in tuberculin a means as efficacious and less dangerous of attaining the same end.

Upon the whole, the resistance conferred by tuberculin and that which is observed in animals or in man already attacked by benign forms of tuberculosis (tuberculosis of the lymph nodes or scrofula, tuberculosis of the bone, or of the skin, lupus) appear to be of the same nature as that which is artificially effected, whether by intravenous inoculation of human or bovine bacilli, following the methods of Behring or of Koch and Schültz, or by subcutaneous inoculation of the same bacilli (Lignières, Arloing), or by the insertion under the skin of collodion sacs containing cultures of human or bovine tuberculosis (Heymans).

In each of these cases it is not a question of true immunity, since the animals thus prepared, although not giving the tuberculin reaction, remain indefinitely carriers of living and virulent bacilli, and these are capable when the resistance begins to diminish of giving rise in the bodies of these same animals to serious lesions.

Let us recall, indeed, on the one side, that in the experiments of Melun (1906) on animals vaccinated with the "bovovaccin" of Behring, the inoculated bacilli were proved not to be absorbed at the end of six months (Vallée and Rossignol, Moussu), and, on the other hand, that Roux and Vallée have demonstrated that vaccination intravenously or subcutaneously does not protect against infection.

On the contrary, the experiments which I have reported strongly support the statement that by the intestinal absorption of a weak and single dose of tubercle bacilli very finely divided, one can obtain at the same time the total absorption of the bacilli in the lymphatic system, and a state of immunity such that the animals are insusceptible, during a year at least, to large infections through the digestive tract.

Without doubt it is not a matter of a method of vaccination which one could think of employing in preserving the human race from this terrible scourge of tuberculosis. It would be rash to consider as very near a definite solution of this sort. But so difficult a study can proceed only by stages. Following Villemin and Robert Koch, who have laid the foundations upon which we build, a great number of research works have brought their stones. Others will follow, and the work will be accomplished for the glory and for the salvation of humanity.

THE MYTH AND THE MYSTERY OF "MÉNIÈRE'S DISEASE."

By GEORGE M. GOULD, M.D.,

ITHACA, NEW YORK.

Bibliographical.—The titles of some three hundred books and monographs on "Ménière's Disease" have been listed since, in 1861, the Parisian Aurist made his communication to l'Académie Impériale de Médecine. None would attempt a critical reading of all these, but if an emmetropic intelligence should secure a cartload of the more noteworthy and carefully digest them, he would find much to amuse, more to edify, and most to warn. Especially if he is an oculist! But thousands of physicians have, more or less carefully, read much of this literature without suggestion either of pleasure, instruction, or admonition: and most certainly but few of the three hundred intended to furnish amusement, enlightenment, or warning. Leastwise to themselves! The astute reader must find the unconscious fun with some grim intrepidity, must fish cunningly for the unintended profit, and must know a deal more than the writers about pathology in order to be heedful of decayed signboards at every crossing, silently crying: *"Danger! Look and Listen before Crossing!"*

The Legend Begins.—At the session of L'Académie Impériale de Médecine, held January 8, 1861, M. Ménière, Médecin de l'institution impériale des sourds muets, etc., supplied at least an epitome of a study, "sur une forme de surdité grave dépendent d'une lésion de l'oreille interne."* in the following terms:

1. An auditory apparatus, hitherto perfectly healthy, may suddenly become the seat of functional troubles, consisting of sounds of various kinds, continuous or intermittent; these noises are soon followed by more or less deafness.

2. These functional troubles having their origin in the internal auditory apparatus, may give rise to symptoms supposed to be cerebral, such as vertigo, dizziness, uncertain walk, turning, and falling, besides being accompanied by nausea, vomiting and a state of syncope.

3. These symptoms, intermitting in type, are soon followed by more or less complete deafness, and often the hearing is suddenly and completely abolished.

4. Everything leads to the belief that the physical lesion, which is the cause of these functional troubles, is in the semicircular canals.

In a later communication, published the same year, M. Ménière emphasizes the necessity of recognizing that certain apoplectic seizures are not cerebral in origin, but are lesions of the auditory apparatus, which will be followed by incurable deafness. He supports this view by the reports of five cases furnished by others:

Case I. A physician, aged 47, for 15 years had had tinnitus, especially in the left ear; deafness of this ear followed, despite all treatment. The right followed the same course. In neither case had there been a sign of local inflammation, no catarrh of the tubes, etc. For three years the disease had been stationary, when, after a day in the open air, the patient, *while reading* [italics mine], was suddenly seized with violent sneezing; upon rising, he staggered and could not walk straightforward. This continued for three hours, when the man went to bed. In the morning, walking was still more difficult, there was a feeling of heaviness or compression in the occiput, a wheeling of the body to the left, a threatened falling, as if the left side was weak, although, in bed, both sides of the body seemed equally strong. Nausea soon came on, with vomiting often repeated during the day; the stomach could retain nothing. There was recovery in a few days of perfect health, although the hearing gradually lessened. The diagnosis was lesion of the internal ear. Six weeks later there was another attack of vertigo, lasting two days, with great weakness, followed by paresis of the left side, with sudden general recovery, but with lessened acuity of hearing.

Case II. M. Ménière's second case was that of a physician, aged 45, who had tinnitus, following taking of quinine. Hearing lessened, and by and by attacks of vertigo and vomiting came on, which continued for some months, until finally there were falls in the street. Deafness increased. The general health was finally completely reestablished, although the hearing was almost lost. There was no inflammatory or catarrhal disease of the ears. The warning is repeated that the agony of belief in deep-seated cerebral disease endured by so many patients with such symptoms may be relieved by recognition of this, their supposed aural origin.

Case III. A man, probably middle aged, in good health, swooned *in his office*. Nausea and vomiting supervened; everything whirled about him. Noise in the ears was complained of, and some loss of hearing followed. There was no other discoverable sign of disease of the ears.

Case IV. A business man, 40 years old, *always confined to his desk*, in perfect health, swooned while smoking. Nausea and repeated vomiting followed; everything whirled in the room; he was confined to bed for awhile, fearing to fall again. Health soon returned, but there was some difficulty in walking. There was violent and continuous tinnitus, and the hearing was somewhat weakened. He could not go to the theatre as heretofore, and his life, public and private, underwent a change.

**Bulletin de l'Académie de Médecine*, Paris, 1860-1, XVII. I shall not hereafter burden the reader's attention with the usual bibliographic references. They are easily obtained by the serious students of the subject.

Case V. A man, "encore jeune," was seized with attacks of vertigo, nausea, and vomiting. The treatment fashionable at that time (bleeding, purgation, etc.) left the diagnosis "cerebral congestion" (still not out of fashion) doubtful. Hearing lessened, tinnitus was noticed, and unsteady gait, but no ascertainable aural disease existed. A sort of half-faint occurred, the weakness lasting a few minutes only. M. Ménière and his great consultants, Trousseau, etc., could not explain such a happening, and as hearing was a little impaired, the conclusion was that the lesion was in the internal ear. Science is praised for her magnificent progress in the localization of cerebral lesions. A certain conclusion is emphasized that the affection signalized has no relation to epilepsy.

Note in passing, that M. Ménière makes the following unwarranted assumptions:

a. That these "functional troubles," briefly, tinnitus, have their "seat" in the ear. That is like saying that the "seat" of paralysis of the leg is in the leg, or that the "seat" of headache or any reflex neurosis is in the organ noticeably affected. M. Ménière speaks as if he had never heard of reflex action, physiological or pathological. The human body in health and disease is one vast system of reflexes.

b. This tinnitus is "functional," and yet it is followed by "more or less deafness." The cause of this deafness, he assumes, is a physical lesion in the semicircular canals. As every aurist knows, there are multitudes of patients with tinnitus not followed by deafness. And, as has often been subsequently demonstrated, there have been many cases of both tinnitus and deafness not caused by any lesion of the canals.

c. These functional troubles, assumed without proof, to have their origin "in the internal ear," are assumed to cause other symptoms, "supposed to be cerebral," such as vertigo, unsteady walk, turning, falling, nausea, vomiting, and syncope. All of these symptoms, separately, in any pairs, all threes, all fours, all fives, the sixes, and the sevens, often exist without tinnitus, and without deafness, and without any aural symptoms whatever.

d. The lesion of the "internal auditory apparatus" is assumed to be apoplectiform, and yet the "deafness" of M. Ménière's five cases is described as "lessened acuity of hearing" in one, "hearing almost lost" in another, "some loss of hearing" in a third, "somewhat weakened" in the fourth, "a little impaired" in the fifth. And yet he had said in proposition three that "often the hearing is suddenly and completely abolished." The local "apoplexy" is thus assumed, and his clinical cases do not certainly warrant his "suddenly and absolutely abolished." With such a weaving of clinical malobservation, preformed theory, unjustified assumptions, and reckless logic, was the start made.

Epitomes of Case-Histories.—The reports of the cases of M. Ménière "furnished him by others" may be simply and correctly, and adequately, given as follows:

Case 1. A man of 47, who had tinnitus for 15 years, had two attacks of the already universally-known, immensely common, old-fashioned disease, variously called "sick-headache," "migraine," "megrim," "hemicrania," etc.

Case 2. A man of 45 had an attack of sick headache.

Case 3. A middle-aged man had an attack of sick headache.

Case 4. A case of sick headache in a man of 40.

Case 5. A man *"encore jeune"* had attacks of sick headache.

Because the hearing in these cases, not measured or registered before the attacks, was later reported as impaired, the cause is assumed to be apoplexy of the internal ear. But for ages before, millions of patients had suffered from sick headache, with all the symptoms listed, and all about M. Ménière were multitudes of contemporary sufferers from the same disease. The only diagnosis justified by inductive logic and clinical experience was: Sick headache with a continuing sequel of abnormal aural function.

Confusion's Masterpiece.—Besides that of its inventor, the disease has become that of many years and many ears. It is both useless to attempt and impossible to compile an abstract of the confusion ever worse confounded that has characterized the discussion during the last forty-seven years. Assertion has been disproved, contradiction has been contradicted, theories have been set up and knocked down, subterfuges have been exposed, props and even foundations have been undermined—until there is not a statement that can be made concerning the theory of which the exact opposite is not as true. The theorizers have made a sorry mess of it all. Schartze and Grunert in 1895 say that the real nature of the disease is up to now, unknown, and Sugar uses the term, "the confusion of Babel," when speaking of the disease and its exponents and critics. Heerman speaks with sincere regret when, in 1906, he is compelled to let an old theory drop without having anything to offer in its place.

The Experimental Physiologists as to the Function of the Semicircular Canals.—In the histories of cases there were as many symptoms as could be found, invented or exaggerated, of vertigo, unsteady gait, swaying, turning, weakness, falling, swooning, etc., and as it was early decided that according to their three planes and the arrangements of the canals, the labyrinth must be the organ of equilibrium, and that the hemorrhages into it in Ménière's disease caused the inequilibrium, the vertigo, the swooning, and all that. The illogic of this logic was ludicrously apparent, the observation blind, the physiology was unphysiological and the science startlingly unscientific, but that did not, and does not, matter. Thousands of experiments upon animals have been carried out, all without conclusive results. And the vivisection experiments upon man by disease and traumatism, as revealed in the few necropsies, have only added to the mystification. Before Ménière's publication, Flourens, by extirpation of the labyrinth in pigeons and rabbits, had tried to determine the function of the canals, and Ménière found exudate in the case of a girl with symptoms of his disease prior to death. Goltz confirmed Flourens. Breuer's conclusions, confirmed by Mach, opposed those of Flourens and Goltz. Böttcher contends that injuries of the neighboring cerebral organs account for the symptoms, and that the injuries to the semicircular canals are not the cause of the loss of equilibrium. Tomasziewicz agrees to this, and Baginsky, after many experiments, concludes that the accidental and incidental cerebral lesions cause the loss of equilibrium and the forced movements. Kusselbach confirms this conclusion as a result of experiments on fishes. Lucae agrees, and cites a human case with hemorrhage and inflammation of the entire labyrinth, especially of semicircular canals, yet before death there was not a sign of giddiness, etc. Höges disputes Baginsky's conclusions, and Landois and Loewenberg believe that the semicircular canals are controllers of equilibrium. Brunner thinks that the correctness of the Goltz-Breuer hypothesis is established by the double

atrophy of the acoustic nerves, which should produce both deafness and loss of equilibrium. Curschmann confirms the Flourens-Goltschen experiments, although he does not think the canals are the organs of equilibrium. Brunner contends that not loss of the canals, but their irritation, produces loss of equilibrium. The early stages of the disease produce the giddiness which ends with the complete degeneration. Ferrier concludes the canals have a function in hearing. Gellé finds that dizziness can exist for years without any demonstrable abnormality in the labyrinth or ear. Steiner does not find the canals to be the organs of equilibrium. Neither does Ewald. Gallstein says "the hypothesis of the physiologists as to the function of the canals finds no proof in clinical histories," and thinks that cerebrospinal meningitis is the cause of the lesion. Gellé found no effusion present in his necropsies, but did find sclerosis of the windows, which did not yield to pressure, thus producing a "simulated" Ménière's disease. Pengniez and Fournier think the lesion is not localizable in the auditory apparatus, but is a sign of mental degeneration. Necropsies multiply, in which the severest lesions of the inner ear, necroses of the labyrinth, hemorrhages, etc., have not produced a symptom of the so-called Ménière's disease. Conversely, cases are reported in which a tumor of the fourth ventricle produced "typical" Ménière's disease, the labyrinth being normal. Hensen says that after a study of the literature and ten years of physiological experiments, there is no adequate basis for conclusion. Eckert emphasizes the impossibility of decision by physiological experiments, and of carrying out a *pure* experiment, so that there is a chaos of contradictory methods, results, and opinions. Foster thinks the canals are not connected with the sense of hearing, but serve to intermediate the feeling of movement of our head through space, a feeling which, when intense, produces dizziness and vertigo. Baginsky combats this theory, and Högyes combats Baginsky. Cases of Ménière's disease have been reported caused by all sorts of diseases and abnormal conditions of the external and middle ear, cerumen, polyps, abscesses, etc., the symptoms disappearing with treatment. The symptoms of caisson disease are precisely those called typical of Ménière's disease, and the pathology of caisson disease is well known. Many are the instances of complete recovery (including that of hearing) from "typical" Ménière's disease, and far more of a hundred purely cerebral and systemic diseases with "typical" symptoms. Lucae says that physiology and pathological anatomy still owe us a clearing up of this extremely difficult problem, and Frankl-Hochwart is of much the same mind. The investigations of Barnicks, Jansens, Stenger, and others leave the conclusion certain that no conclusion is certain. After nearly fifty years of most diligent investigation a supposed disease of a supposed single small organ without a single definite result and without any pathology whatever, must be either mythical, or of functional and reflex origin.

The Symptomatology. — Voury's "Professorial Guide" gives the number of symptoms as twenty-one: (1) Sudden vertigo, (2) vacillation, (3) loss of consciousness, (4) return of consciousness, (5) headache, (6) obscuration of vision, (7) giddiness, (8) loss of equilibrium, (9) propulsion, (10) paleness, (11) sweating, (12) cold skin, (13) nausea, (14) vomiting, (15) confinement to bed, (16) tinnitus, (17) deafness, (18) absence of fever, (19) return of health, (20) deafness persistent, (21) series of attacks.

The inevitable differences in the symptoms of the cases reported as morbus Ménière, and the consequent startling impossibility of getting all into the procrustean bed soon necessitated a vigorous lopping off of the overlong and overnumerous members. It was a reckless surgery, but without it the minds even of the theorizers balked, and poor Typical Disease was got to bed under the strabismic names of "Ménière's syndrome," Ménière symptomcomplex," "Ménière's triad," "Ménière's symptoms," "Ménière's vertigo," "morbus Ménière." It is difficult to understand why it has not been called "Ménière's vomiting," "Ménière's swooning," Ménière's propulsion, his gait, his sweating, his headache, or even by the too suggestive name of his "vacillation." Ménière's compulsion, or Ménière's obscuration of vision, it might well have been dubbed.

In 1872, Kroll gives the pathognomonic symptoms as sudden outbreak of acute cerebral symptoms, deafness or impaired hearing, spontaneous disappearance of cerebral symptoms, with continuance of the deafness. Bonnenfant's Professor, in 1874, warned that the pesky symptom, vertigo, is common to many diseases, but pathognomonic of none; and he then proceeds to the amazing statement that nausea and vomiting is seldom seen except in Ménière's disease. Voury's definition is, "An affection of the internal ear characterized by deafness, tinnitus, attacks of vertigo, usually accompanied by severe troubles of equilibrium, a state of syncope, nausea, and vomiting." To get the clinical order of the symptoms absolutely reversed was necessary if the very big patient, Morbus Ménière was to be got upon the very little bed. Voury finally decides that a proper patient has and must have, at least three symptoms—deafness, tinnitus, and vertigo. The headache, vomiting, and a long kite-tail of etceteras, were hacked off, and of the astonishing number of ocular symptoms present there was never even a whisper. Kroll avers that "the diseases of no organ more frequently cause cerebral symptoms than those of the ear, and vertigo is the most frequent"—a bit of the finest humor. Rare qualms of the scientific conscience are occasionally exposed in the avid ease with which our ancient, ever living and ever present "rush of blood to the head" ("cerebral congestion"), and the still vigorous "stomach vertigo" are deftly left out of the accounting. The unimportant *vertigo* takes the throne while the all-important *headache* and *vomiting* are waved into banishment. Swooning, propulsion, pallor, sweating, and many others died aborning. And so the triad at last is settled upon as (1) deafness, (2) vertigo, and (3) tinnitus (inversely, again, as the square of the distance!). But —a useless *but* of course—thousands of patients have either one alone; thousands either two; a few may have all three. "But at least the patient is deaf!" By no means! Lots of cases are on record in which typicality was otherwise all that could be desired except that the deafness was either only slight, never complete, or entirely recovered from. At least in such Alice's Cat has entirely disappeared and only the grin remains. And how about the astonishing majority of all cases proceeding to absolute deafness in which all other symptoms of the "syndrome" disappear? Why also absolutely overlook the great world of those deaf from any and all causes who, besides the deafness, never show the other symptoms?

"The Organ of Equilibration."—In a normal condition the semicircular canals are supposed to be the organ which govern the sense of equilibrium, of the position of the body, or of the movement of

our head through space. Under the abnormal conditions of apoplexy, traumatism, contiguous or neighboring disease, whirling, etc., the sense of equilibrium, position, motion, etc., is partially or wholly lost, and tinnitus, vertigo, and partial deafness, etc., supervene. But when the organ is destroyed, its assumed functions must not only be morbid, but wholly abrogated. And yet none speak of this and all ignore the fact that the patient passes from view—*i.e.* stops reeling, vomiting, etc., and ceases to be vertiginous. A child, surely a first year medical student, must see that in the light of such facts the semicircular canals are not the chief or only organs of equilibrium. James' experiments with deaf mutes are designed to show the relative immunity of deaf mutes from dizziness. Of 519, 186 were not made dizzy by whirling, 134 were made only slightly dizzy, while 199 were normally sensitive. While of 200 normal hearing persons only one was exempt.* In the name of all the great physicians not in the "Index Catalogue"—of all the great men not in "Who's Who"—what is the teaching of these facts? Frankly, nothing! But if anything at all it is surely not that destruction of the organ of equilibrium leaves the function of equilibrium uninfluenced and actively functional—"normally sensitive," in at least 199 out of 519. And so of the foolish experiments of revolving a man like a wheel in a machine (instead of dervish-wise) those with destroyed organs of equilibration should not show any more nor any less a sense of equilibrium than when not whirled. How can a subject with a single organ of equilibration ever, and under any circumstances, have any sense of equilibrium when it is destroyed? To cap the climax of absurdity, how under the theory, can a whirling dervish have any sense of equilibrium during or immediately after an hour's spin? All the mutilating experiments upon fishes, tadpoles, pigeons, etc., teach absolutely nothing, except the uselessness of experiment and experimenter. How could a clumsy endolymph with its acoustic hairs help a couple of birds to regain equilibrium, when playing or fighting amidst the branches of tree or shrub? A hundred motions in every possible attitude of the head are executed with lightning-like rapidity and precision long before such a mechanism could direct wing and eye. In the case of birds, it is of course the eyes that are the chief organs of equilibration. It seems stupid to add that the labyrinth is surely not the chief or only organ of equilibrium. Had it been studied by observant and clinical understandings instead of by theorizers and laboratory experimentalists its patent function would a half-century ago have been so evident as to need but a sentence to set it forth. It is, I fancy, plainly the device for protecting the delicate and complicated mechanism of hearing from injury from violent concussions and manifold injuries due to harmful air-pressures either from without through the meatus, or from the accidents of vomiting, sneezing, eating, etc., through the Eustachian tubes. The round and oval membranous windows and the peculiar geometrical arrangements of the canals, the endolymph, etc., are all strikingly and admirably adapted to withstand and equalize strains and violences from sudden or extreme aerial blows and stresses. Brewer suggestively says gravity exerts its constant influence on our limbs, although the canals are destroyed, and it tells us where the ground is and where the zenith.* Helmholtz had an adumbration of this truth when he held that the nerves of the vestibule and the ampulla are those of noises, and those of the organ of Corti are for musical sounds. As to what really is the organ of equilibrium, the answer seems to be as clear and decisive; it is that of nearly every muscle ("muscle-sense") and nerve, and sensation of the body, mediated by the cerebellum, but chiefly those of the eye. This presupposes the admirable truth, called by Sherrington, "the integrative action of the nervous system." What, *e.g.* but that, does the swaying and incoordination and even the falling of the ataxic, signify? His disease of the deprivation of the quick sense of pressures and delicacies of sensations upon the soles of the feet, etc., normally carried through a hundred muscles and nerves, fail to notify the man with normal labyrinths, but with abnormal and sclerosed cord-strands, of the poise of his body—*especially if his eyes are closed.* And many such instances and illustrations will illustrate the truth, had science been clinical instead of theoretical and experimental.

In the Blind Alley and Why.—The profession and the "leaders" who have led it into this blind alley are in a sad plight. To go forward is impossible, to go backward is shameful. The most careful and philosophic are saying that at last we must renounce entirely the absurd eponymic, Ménière's disease, etc., because it is ludicrous. The despairing are nagging the experimenters to read the riddle right which has been read wrong, and everybody is looking for some apparently hopeless way out of the impasse. A glance at the far sources of the blunderings should not be amiss:

A. A great and true scientist, Tyndall, speaking of so-called scientists, says: "We often complain of the scorn of theories by practical men, and to convince them we triumphantly point to the immense services of our heroes. The practical man, however, will not be convinced; and why? Simply because of ten well-known theories nine deserve nothing better than contempt. Our intellectual heroes build their theories upon enduring facts; the mass of facts which they use in order to guess the law is a measure of individual ability, not the touchstone of the correctness of their system."

Reviewing the literature of the past ten years in 1906, Herman finds the whole affair more than doubtful and speaks with justifiable irony of the tough vitality of the baseless theories of medical history.

In physics, in the pure sciences, the mistakes of nine theorizers are expensive only speculatively, and the "working hypothesis," at the best and worst, can only delay the final appearance of the truth. But in medicine, every false theory is a tragicaled vivisection experiment, multiplied and manifold upon the great patient Humanity. The demonstration of the falseness of a false theory is at the direct cost of human lives and suffering—and chiefly, too, because it results in the indirect result of therapeu-

*A man so frank as James confesses that "obviously conditions are complicated," and "curious exceptions exist which I cannot understand." De Champeaux thinks seasickness through primary stomachal diseases produces Ménière's disease, while Guye concludes that seasickness is a symptom of Ménière's disease.

*Herman was frankly opposed to the belief that the canals are the organ of equilibration, movement, etc., and concluded that "the senses in the arrangements of the body are wholly sufficient to account for the feeling of equilibrium, movements, etc., because every movement, in consequence of the feeling of weight, centrifugal force, etc., must reach consciousness even after shutting off the sense of sight, by pressure of the movable parts against the static ones. Moreover, there are the influences of the muscle sense, the recognition of the surfaces of the body against the media about it"—so that "the supposition of a special sense organ for the perception of movement is not necessary."

tic nihilism, and the simple continuance of diseases from which the attention is turned away. Sick-headache, or "migraine," is the present greatest, most health-wrecking, most ruinous of all modern diseases. Even supposing Ménière's disease a real nosologic entity, it is almost infinitely rare, as compared with "migraine." But sound observation, and a clinical attitude of mind instead of a theorizing mania, would, in 1861, and in any of the years since, have shown that old-fashioned sick-headache is the predominant and dominant cause of the whole pother about morbus Ménière.

B. The "Typical Case" Obsession.—Even in the infectious and organic diseases, no case was ever exactly like another. In all functional diseases, far outnumbering all others, the symptomatic differences are vastly more noteworthy than the resemblances. Every case is peculiarly, persistently, and almost totally unlike every other.

C. The Disgrace of Malignant Myopic Specialism.—In these 47 years not a physician, not an oculist has thought of the eyestrain-caused "migraine" as the cause of the disease of Ménière. For the personal profit of the specialist the human body has been parcelled out and farmed out in little patches to men with no knowledge of the great truth of the integrative and unitizing action of the nervous system. The leaders of such specialties make mighty haste to forget the true fable of the belly and its members, and besides deny the fact of morbid reflexes in all and through all. They fill their ponderous text-books with erudite theories, for example, of the mathematics of optics, and utterly ignore the ametropia that is cursing and killing at least one-half the world, and three-fourths of the world's sick. No Ménièrist ever seriously asked what causes the tiny localized hemorrhage into the labyrinth, and only fools and fanatics ever tried to show that "migraine" is surely caused by eyestrain and easily cured by glasses.* And for 47 more years the cynical general physician and pathologists will join in the laugh at the loony who believes that migraine is the single sole source of all Ménière "triads," "complexes," "syndromes," and "diseases." But it is true and will be plain to all some time.

D. Sticking Fast in the Mud of Medical Ignorance and Bigotry.—In the year 1853, a scientist of the true kind, Dr. Beauperthy, published in the *Gaceta Oficial de Cumaná,* the results of arduous microscopic studies of the blood of yellow fever patients, and almost completely, in all essentials accurately, established the truth that the disease is due to virus inoculated into man by mosquitos. In 1856 he communicated his discoveries to the Académie des Sciences. Strangely enough, he was allowed to do so. More strangely, he was not opposed, or reviled, or martyrized. He was simply ignored, ignored utterly and absolutely. The matter and the man were not worth even the scorn of mention. In the year of Beauperthy's communication, there were taking place thousands of deaths from yellow fever and they continued for 40 years. According to the official British Encyclopedia, Dr. Charles Finlay was the discoverer, in 1881, Beauperthy not being mentioned. According to the medical profession, professors, and official journals, the discoverers of the mosquito-rôle were years afterwards, Read, Lazear, and Carroll.

According to the official advisers and generals and honorers of the medical profession, Jenner was the discoverer of vaccination, but a thousand dairy folk had long known of the immunizing powers of cowpox; and Jenner waited 22 years before he dared repeat the inoculation of the cowpox virus on the Phipps boy which the old Dorsetshire farmer, Jesty, had made on his wife and two children. And Jesty dared also what Jenner did not dare, to inoculate the members of his family subsequently with genuine smallpox virus. And Jenner had to fight the truth into the heads and hearts of his scientific contemporaries and aftercomers.

In 1843 Holmes, and in 1845 Semmelweiss, contended that puerperal fever was a contagious affection. This was too much for the leaders and official judges, Hodge, Meigs, & Co., who proceeded to silence Holmes and Semmelweiss, the one by opposition, the other by martyrdom, and again a generation passed with many thousands of unnecessary deaths, caused by medical bigotry.

Long ago a number of men became convinced and openly said that migraine and many other diseases were caused by the eye-strain of ametropia. Some at once saw their blunder (the leaders of the profession would not accept the truth) and in blind self-stultification afterwards did what they could to oppose the truth. Others have since been fervently and secretly beseeching their god for forgiveness that, once and for a day, they dared to espouse an unpopular cause.

A hundred such examples could be added. To what good! And yet the mosquito is the means of conveying the germs of yellow fever; vaccination has prevented millions of deaths; puerperal fever was carried by the doctor; and migraine, the world's commonest and worst disease to-day, is caused by eyestrain; and it is the cause of Ménière's disease.

E. Love, the Guide.—The prayer of Maimonides, as well as the tradition of the profession, is that "the truth," "science," physician and profession, exist solely for the benefit of the patient, that therapeutics and prevention of evil come not from ambition and self-seeking. Medical science becomes ignorance and confusion when disconnected from the patient, present or to come. True success lies in work for the relief of the individual patient, and of the infinite patient, Humanity. The Ménièrists seem to have taken very literally as their rule Lessing's famous preference and desire for the everlasting search for truth rather than for truth itself. Once, indeed, M. Ménière seemed to have a little thrill of sympathy for the patient who, by his discovery, should be relieved of the incubus of the fear of incurable cerebral disease, replaced by that of incurable aural disease. After that, the dream faded into the light of common day, becoming the fateful system-building attempt at poising the unstable cone of science on its apex, a million animal experiments, and the establishment of a pseudo-disease of which there was no possibility of cure and no desire of cure. A chapter on the history of the therapeutics of Ménière's disease would be more amusing than the story of Mark Twain's "Jumping Frog." If any one of these hundreds of erudite writers could have dropped their pens and with sympathy watched a patient during the awful seizure of a vomiting convulsion! The truth would have been caught, even despite the blinding power of the theory of cerebral disease. "The Kingdom of Science" said a great scientist "cometh not by observation and experiment

*Two neurologists recently report 1,700 cases of migraine cured by scientific correction of ametropia, and at the same time, presidents, chairmen, "leaders" in ophthalmology publish their ignominy and shame (that they cannot diagnose ametropia and so cannot cure a single case of migraine) that the only certain thing about migraine is that it is *not* due to the eyes! The only certain thing about such scientists is that they never prescribed a correct pair of glasses.

alone, but is completed by fixing the roots of observation and experiment in a region inaccessible to both, and in dealing with which we are forced to fall back upon the picturing power of the mind."

To understand the outworking of these factors, let us glance at the overlooked and underlooked symptoms of the Ménièrists.

Tinnitus and Deafness.—These symptoms served to cause the specialists in charge to consider the organ of hearing as the primary one affected. Ignorant of the integrative-action truth, they could not dream that the original source of the local aural symptoms could be in another and distant organ. And being obsessed with the crude organic pathology theory of the origin of all diseases, they again could not even think of a faraway functional source of the disease. Being physicians, they had adopted the ages-long, incomprehensible, batlike blindness of the whole world that the eyes, the most marvelous and useful organs of the body, could not be the source of any systemic or distant disease. Now it is as true as truth can be that there are millions of sensible people in civilization who have tinnitus of all kinds and intensities, without sequent deafness, or vertigo, or any of the 20 or 30 other symptoms of M. Ménière and his followers. Many people can at will create a severe tinnitus by making tense certain muscles of the eyes; "setting" the muscles of the neck, of the throat, etc., will produce the same roaring in the ears. A certain number of cases of persisting tinnitus are caused by too much smoking. One patient had severe tinnitus in eating, with every motion of the jaw. It is as true that thousands of the deaf never had tinnitus, or vertigo, or the rest. To pounce upon the few who happened to have the tinnitus alone with some little or much deafness and shout it into a nosologic entity, is certainly not clinical or inductive science—most far from it! Beyond question, the tinnitus and deafness may be caused by injury, exudate, hemorrhage, etc., into the middle and inner ear. But when it is so, it is the greater duty to seek out the cause of the morbid local condition.

If the canals are the organ of equilibrium, etc., and other organs of the ear are those of hearing, why does injury of the canals produce the one distinguishing symptom, deafness? Why so little attention, practically none, to the real organ of hearing? Partly because it is usually not found to be diseased, but more, because a preformed theory must be proved. Some of the great text-books on diseases of the ear refuse to allow Ménière's disease but a brief and skimpy mention, and Politzer begs pardon for including it.

If the oculists of the world had been clinicians and observers, instead of theorizers and specialists, they could and would have long ago told the aurists that eyestrain sometimes has its morbid functional reflex to the ear, and sets up even the most unendurable and persisting tinnitus. I have had a number of such cases besides that set forth in the *Maryland Medical Journal*, April, 1905, and in "Biographic Clinics," Vol. V, p. 67. That the local aural lesion causing the deafness secondarily produces the vertigo, the headache, the nausea, and vomiting, etc., is wholly without clinical proof, and is indeed the reverse of the truth. That the vertigo produced the aural troubles is but little more credible. Tinnitus was retained in the Ménière symptom-complex in order to help poor Deafness to preserve the disease as an aural one, although either exists as often alone as with the other.

Vertigo, Staggering, etc.—That vertigo has been retained as one of the symptoms necessary to constitute the typical disease is evidenced by the fact that the disease is not seldom called Ménière's vertigo, or labyrinthine vertigo, etc. As a symptom, it was retained in the "triad" to exaggerate the rôle of the ear, although local aural disease rarely or never causes vertigo; although vertigo may continue with absolute deafness; although vertigo without aural disease is a million times more frequent than with it; although vertigo is plainly caused by a hundred extraaural diseases; although the cases of vertigo from eyestrain far outnumber those from all other causes combined. The symptoms of staggering, propulsion, impaired gait, etc., allied to, or extremes of giddiness and vertigo,* were much made of in the early reports, but have been less and less bespoken as it has become increasingly evident that they had no logical place in the complex, and the illogicalities, even of the retained three, in the struggle for existence, were sufficiently tormenting to the theorizers; and so the staggering, etc., had to be dropped.† Lucae and others confess that the conditions in which canal disease can produce vertigo are "*volkommen dunkel.*"

Swooning and Falling, as symptoms of morbus Ménière, were also early in evidence, and, like staggering, etc., often occur in the miscalled Ménière's disease (*i.e.* in the explosive kinds of sick headache) which were supposed by M. Ménière and his followers to constitute their new disease of the semicircular canals. The swooning and faintings, or even the symptom of suddenly falling unconscious, are indeed not uncommon, though not of course the rule, in sick headache and other cerebral neuroses of eyestrain. As results of eyestrain, we can understand their *raison d'être* logically, just as we often see them clinically. I have certainly had a score or more of such cases, illustrating what I have called the explosive type of migraine, cured immediately by scientific spectacles. They had more or less or all of the twenty-one symptoms of Ménière described by Voury. I have reported a few cases, but it is useless to argue, or illustrate, or plead in the present temper or distemper of the professional mind. But if swooning and falling, etc., could not be believed the results of abnormal ocular function, they could of course gain speedy credence when reported as following a drop of blood in the labyrinth of the ear. The genuine Ménièrist has by no means given them up to-day, but the more cautious and inductive investigators will not allow them to be added to the three sacred symptoms still so desperately clung to.

Headache.—Even this symptom, which every specialist and internist, every surgeon and manicurist, claims as his especial property, which characterizes every disease that ever existed or that never existed—even this thermometer and barometer and hygrometer of the medical weatherman, the more careful Ménièrists have had to exclude from their symptomatological trinity. Because, as before, it was difficult to see how the walled-off canals, even when hemorrhagic, could beget dire implication of the entire brain. Clinically, the refractionists, finally, have been able to demonstrate that headache, except in a tiny minority of cases, is peculiarly theirs, because, if they will, they can cure it. Sometimes, indeed, it coexisted with "typical" cases of Ménière's disease, but it persisted and recurred when the slight

*One advises surgically produced deafness to stop the vertigo!

†Learned authorities have reported cases of Ménière's disease in horses, one in a dog, and Lillman solemnly describes a typical case in a cat, which had "vertigo, shook its head, *miaute jämmerlich*, and became deaf." "There was no doubt of the diagnosis," he says!

deafness passed to complete deafness, and when the tinnitus ended. It was wrong for it to do so, but it was obstinate, and headache had finally to be excluded from the twenty-one, leaving the "three little Indians," Deafness, Tinnitus, and Vertigo, "standing in a row." If now the third, then the second, and, at last, the first should toddle off to join the other deserters there would be left—"none." But the big Chief around which the deserters rally is:

Nausea and Vomiting.—So far removed is the labyrinth from the vomiting center in the medulla that, although in the vast majority of the reported cases of Ménière's disease, vomiting was painfully present as the early and chief symptom, it became utterly impossible to see how the local labyrinthine lesion could set up such a marvelous and widespread convulsion of the organism. For one who is determined to bolster up a preconceived theory, for one who finds that "the diseases of no organ more frequently cause cerebral symptoms than those of the ear," the convulsion is easy of explanation. But a careful clinician will find it decidedly not so. And even the careless ones were early compelled to let this symptom go over to the enemy. Had they scrutinizingly watched him and his doings, they, one and all, might have read the riddle of the mystery of Ménière's disease, because he took with him the sole strength and support of their cause. For it was a rare incident and accident of vomiting that produced the single and genuine lesion which gave temporary but real warrant for the establishing of a distinct type of disease.* I exclude, of course, those cases due to sneezing, violent falls, blows, concussions, etc., which would mechanically wound or break or injure the delicate mechanism of the drum, the middle, or the internal ear. These things, to be sure, do produce true Ménière's disease—a few cases. But the same results are also produced by the vomiting of migraine which is as violent as that of any of these outside concussions, blows, falls, etc. If every writer on Ménière's disease could but once have personally endured the agonizing and terrible violences and exertions, almost beyond the resisting powers of the organism, suffered during migrainous vomiting, the explanation of the Ménière portion would have been discovered in 1861, and in any year thereafter. The intensity and awfulness of the acts and strains are pictured graphically by the early writers, the pallor, writhing, groaning, the agony, the sweating, the utter exhaustion and even coma afterwards. The jaws are wrenched wide as if by a giant, the muscles of the head and neck, those almost of the entire body are convulsively tortured or set, the eyes bulge, and all the conditions meet for injury to the delicate mechanisms of the ear. The vomitus is hurled as if from a deep volcano against the pharynx and the distended and gaping orifices of the Eustachian tubes. And not alone the vomitus, but first, a wild tornado of ejected air and gas, with a concussive violence compared to which that of the Politzer inflation is the softest zephyr. And yet the good aurist warns of the danger of the Politzer bag, and knows of cases aplenty in which the drum has been ruptured and irreparable injury done by it to the ear and hearing. "Soon," say the Ménière reporters, "soon or immediately after the attack of vomiting the patient complained of tinnitus, hearing was found to be impaired, and deafness increased or became complete." Should it not have been glaringly evident to clinicians and aurists, why there was roaring in the ears and deafness? Why do cannoniers find it necessary to plug the external meatus with cotton and keep the mouth closed? Or, if the ear is not plugged, to hold the mouth wide open? Why does a box on the ear sometimes cause tinnitus, disease, and deafness? The propulsive force of the air-current and vomitus against the pharynx and mouths of the Eustachian tubes, as it turns by reflection at a right angle, is far greater than the blow on the external ear and there is no closing possible of the open road to the middle-ear and all its tiny, delicately adjusted mechanisms. The prone or even head-downward position increases by gravity the vasomotor tension and the danger to ears. The vomitus and air is shot out of the mouth and even through the nostrils—but not all of it, for the borbardment of the middle-ear is inevitable.* Is it any wonder that in the few necropsies that have been made (the stapes being against the oval membrane of the semicircular canals) the canals should be found with lesions explaining the tinnitus and deafness? The wonder is that in view of the millions of cases of sick headache there have not been thousands upon thousands of "typical Ménière's disease."

The Components of the "Syndrome."—Thus with minds fixed upon the aural symptoms of the disease, the Ménièrists, as we have seen, more and more neglected the many other precedent and synchronous symptoms and elements, and finally came to lay emphasis only upon the deafness, tinnitus, and vertigo. The vertigo was theoretically retained despite its frequent actual absence in cases, simply because of a false and snapped-up theory that the labyrinth was the organ of equilibrium. The attention was not upon the functional cause of the supposed disease, because, in obedience to organic and gross-lesion pathology, the effect alone interested. The attention was not fixed upon prevention of the disease, and its cure, because theorization, typicality, and disregard of the individual patient and his suffering had excluded the personal sympathy, and "the roots of observation and experiment were not fixed in a region inaccessible to both." Thus the last, and final stage of the disease, deafness, was placed first in the list of symptoms, and in all the later reports the order in which the symptoms actually appear was reversed throughout the list. That is not science, which is, first, the careful observation of facts, and second, the rigid induction of principles or laws from the observed facts. It is not medical science, because no Ménièrist ever cured or prevented the disease in a single patient. Brunner alludes, in passing, to the possible explanation of a "vasomotor neurosis similar to migraine." And Frankl-Hochwart alludes to "pseudo-Ménière's disease due in occasional cases to migraine or its hemicranial equivalent." He also speaks of a "neurosis of the labyrinth." Another way in which the facts compel a later writer to think of migraine and yet slide away from it is shown in one who is a violent opponent of the eyestrain origin of migraine or of anything, and yet who could not wholly assent to the Ménière philosophy. In the *Medical News* of March 26, 1908, Dana describes

*The ages at which the onset of Ménière's disease came in the early cases reported are significant. They are as follows: 47, 45, 40, 40, 32, 38, 43, 62, 60, 52, 51, 28, 38, 45, 52, 35, 46, 45, 47, 40, 60, 44, 52, 58,, 53, 36, 50, 60, 36, 29, 54, 41, 55, 43, 37, 60, 51, 38, 42, 51, 40, 60, 41, 32, 47, 40, 42, 38, 45, 47, 50. The average is about 45½ years, precisely the age of the incidence and of presbyopia, when the previous eyestrain is greatly increased by failure of the accommodation.

*Other causes of vomiting, of course, than that due to eyestrain may produce traumatisms in the ear, and other causes of the traumatism, sneezing, blowing the nose, falls, concussions, diseases, etc., may as certainly cause the aural lesions.

a case of old-fashioned sickheadache which he says was a "migrainous neurosis," or a constitutional neurosis. "As in other cases I have had, the migrainous tendency located itself upon the 8th nerve and produced disturbances of its function!" What caused the "migrainous tendency? An equally good explanation, and an older one, was "God," or "the devil," or an "evil spirit."

To the Ignorers, Deniers, and Sneerers of the Advocates of the Eye-strain Cause of Ménière's Disease, a useless word or two of warning should be added:—No medical or scientific discovery was ever accepted by the so-called leaders and official judges of the matter, and the truth finally came to recognition and acceptance despite their bitter opposition. "Where the mind of genius," said a giant intellect, "discerns the distant truth, which it pursues, the mind not so gifted often discovers nothing but the extravagance which it avoids." The most common and most health-wrecking, most life-wasting, of all diseases is "migraine" or sick-headache. Call that extravagance and exaggeration if you will. It is equally certain that the cause of migraine is eyestrain, and that it is the easiest cured and prevented of all diseases.* "Exaggeration and Extravagance," No. 2.† Finally the symptoms of a large proportion of migraine cases are precisely those of all well reported cases of Ménière's disease.‡ In those reported by the Ménièrists the aural injuries following the traumatism of the terrible vomiting are known and noted without suspicion of their cause, and in those seen by the general physician and oculist, vomiting is well known, but the aural injuries from vomiting are neither known nor noted. Add the two sets of ignorances and knowledges together, and the pother is at an end. It usually takes about 40 years for a great scientific or medical discovery to wear out official opposition and prejudice. The rôle of eyestrain in the production of migraine and nervous disorders was announced 36 and 33 years ago. Already the opposition of the "leaders" and professors is becoming exhausted and they are beginning to accept—of course without a word of thanks to those whom they have ignored and cursed, without a word of public confession of their blundering and shame, and with grim determination to treat the next upstart discoverer with martyrdom.

Ménière's Disease Is Simply "Migraine," or sick headache, with many symptoms ignored and with three of the secondary or incidental effects of migraine over-emphasized:

A. Vertigo.

B. Tinnitus (*a*) of a purely functional neurotic nature, a reflex-ocular neurosis to the center or to the organ of hearing. (*b*) Of traumatic origin caused by vomiting.

C. Partial or complete deafness, due to injuries in vomiting.

Migraine is one of the evil effects, the most common and the most important of eyestrain, always preventable, almost always curable by scientific spectacles, because in almost 100 per cent. of cases it is due to ametropia.

*But not by "the leading ophthalmologists" of the world. Scientific and expert refraction they know not of, and care not for.

†Despite the hideous and stultifying articles by oculists and neurologists that the disease is "rare," its "nature unknown," and that the eye has nothing to do with it, two neurologists have lately reported its cure by scientific spectacles in 1,700 cases. Many physicians and thousands of patients know that ametropia is the cause. I have cured at least six thousand patients.

‡Even in the ignorers of eyes as pathogenic organs the early Ménière reporters could not help mentioning at the onset of the seizures in the case histories such facts as these: "Often the inequilibrium was worse with closed eyes"; "illusions of sight"; "intellectual work"; "visual troubles"; "insomnia"; "nervousness"; "conjunctiva congested"; "looking intently"; "looking upward"; "driving a nail"; "reading while eating"; "iron band about the head"; "writing at table"; "looking downward"; "amaurosis"; "dimness of vision"; "phosphenes"; "diplopia"; "monocular diplopia"; "unable to read with one eye"; "looking at bright light or at the sun"; epiphora"; "blepharospasm"; "acrimation"; "orbital pain"; "couldn't sew longer"; "couldn't see"; "as if seasick"; "stomachal vertigo"; "rush of blood to the head"; "looking at moving things"; "purulent iritis"; "with eyes looking straight forward he walked steadily, but when he turned his head to either side he tended to fall"; "with open eyes he stood quietly, but with closed eyes he would have fallen"; "associated with ocular symptoms"; "muscæ"; "strong sunlight"; "bright day predisposed to an attack"; "eyes ached"; "writing at desk"; "blue spectacles"; "photophobia"; "could not face the light of a lamp"; "no attack when he did not work"; "a severe bilious attack"; "vertigo relieved by closing the eyes"; "vertigo due to high power spectacles"; "nystagmus," etc.

THE EPILEPTIC VOICE SIGN.*

By L. PIERCE CLARK, M.D.,

NEW YORK,

SENIOR ATTENDING PHYSICIAN, HOSPITAL FOR NERVOUS DISEASES OF NEW YORK CITY; VISITING NEUROLOGIST TO THE RANDALL'S ISLAND HOSPITALS AND SCHOOLS; CONSULTING NEUROLOGIST AT THE MANHATTAN STATE HOSPITAL, N. Y.; CONSULTING NEUROLOGIST AT THE CRAIG COLONY FOR EPILEPTICS, SONYEA, N. Y.;

AND

E. W. SCRIPTURE, Ph.D.(Leipzig), M.D.(Munich),

NEW YORK,

FORMERLY DIRECTOR OF THE PSYCHOLOGICAL LABORATORY OF YALE UNIV., AND LECTURER ON PHONETICS AT THE UNIV. OF MARBURG (GERMANY); NOW VISITING PHYSICIAN FOR SPEECH DEFECTS AT RANDALL'S ISLAND; ATTENDING PHYSICIAN AT THE HOSPITAL FOR NERVOUS DISEASES OF NEW YORK CITY; LECTURER ON THE VOICE AT THE NEW YORK INSTITUTE FOR MUSICAL ART, ETC.

VARIOUS[1] characteristics follow different nervous affections, thus we have tabetic gaits, the posture of paralysis agitans, the mental stigma of epilepsy and hysteria, and the like. It seems probable that there are characteristic functional stigmata in the voices of persons suffering from nervous and mental diseases. The characteristic speech of paresis and the thin high-pitched voice of paralysis agitans are well known and readily recognized by all. A more definite analysis of these speech and voice types ought to be made. Many of us have observed in a crude way that there is something very peculiar and distinctive in the epileptic voice. The defect is shown in the expressionless quality of the voice; it renders the epileptic incapable of singing beautifully or speaking well. To one who has lived in a large colony for epileptics for several years the alteration of the epileptic voice is both striking and obvious. With a view of analyzing the voice of epileptics the newer methods of voice study were applied, and we now present what we venture to term the "epileptic voice sign." It is unnecessary to say that there is no past literature to refer to in such studies, as both the problem and its results are entirely novel.

Briefly stated, the method is as follows: The patient speaks into a mouthpiece that covers his mouth rather tightly; this is connected to a small metal cup, the tambour. The top of the tambour is covered with thin rubber that yields to puffs of air and vibrations. A lever connected to the rubber receives the vibrations on a rapidly revolving smoked drum or kymograph, as indicated in Fig. 1. The arrangement can be conveniently called the "tambour method."[2]

*Read before the N. Y. Neurological Society, Nov. 12, 1907.

The character of the resulting curves can be best illustrated by explaining an example. The record of the words "mostly at night" is shown in Fig. 2. The first sound is "m," which is indicated by the flat portion of the wavy line. The gentle rise of the wavy line corresponds to "o," the steep rise to "s." The sudden fall is due to the "t." The bit of straight line in the middle is also due to a "t." The record ends with a "t." This "t" ends in the usual way with a strong puff of air, which appears in the record as a sudden upward movement of the line.

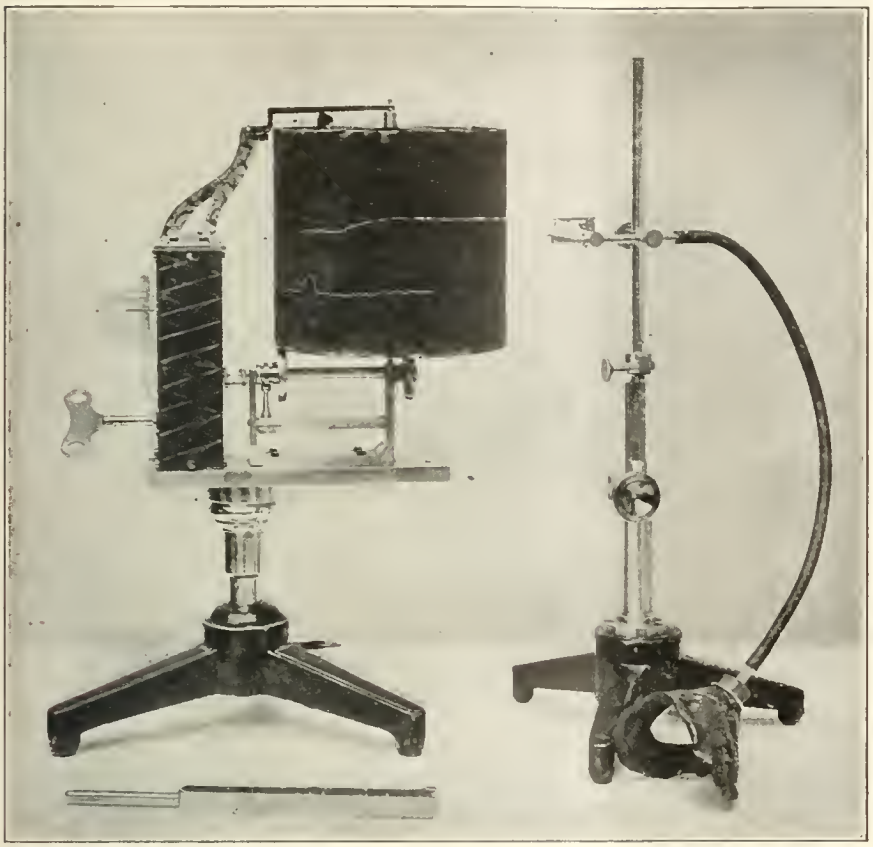

Fig. 1.—Arrangement of Apparatus for the Tambour Method.

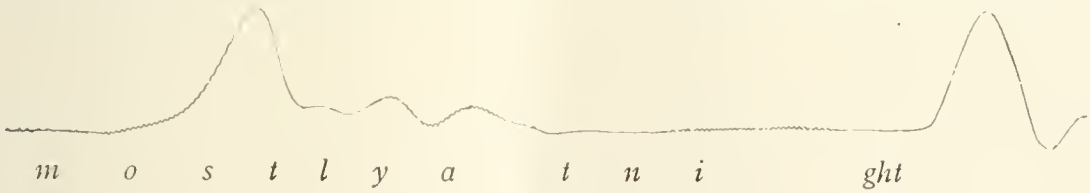

Fig. 2.—Record of "mostly at night."

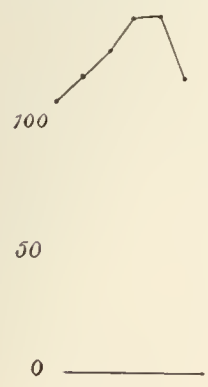

Fig. 3.—Melody Plot.

In sounds like "m," "o," "l," "y," the larynx vibrates. These vibrations produce wavy lines in the record. A long wave indicates a slow vibration, a short wave a quick one. Slow vibrations correspond to low pitch, quick ones to high pitch.

Each wave of a record is measured and the pitch is calculated. For example, the first six vibrations of "m" measured 1.3, 1.2, 1.1, 1.0, 1.2 mm. The calculations give a pitch of 110, 119, 130, 143, 143, 119 vibrations per record. That is, the first vibration corresponded to a tone of 110 vibrations; the second to a somewhat higher tone, the third to a still higher one. The successive pitches are plotted on millimeter paper, as indicated in Fig. 3. A line connecting the tops of the ordinates is termed the "melody plot." In this way the entire record is worked through.

In Figs. 4 to 6 we have the melody plots from a normal voice. In Fig. 4 we have a record of "rather cloudy." We see the melody of the first part of the word rising rapidly; thereafter it moves more or less up and down, falling at the end. In Fig. 5, "about two o'clock," a similar continual change in melody is apparent. In Fig. 6 we notice that the melody of the first vowel in "pretty" rises and falls. This is an illustration of a fundamental law of normal speech established in previous researches,[3] to the effect that every vowel used as a unit has a circumflex, that is, a rising and falling melody. The last portion of the phrase "y good" in Fig. 6 all has changing melody; the curve rises and falls in several fluctuations; there is a deep fall at the end.

The remaining curves are a few out of a large number of similar ones from epileptics. The peculiarity in the melody strikes the eye at once; instead of the continual rise and fall in melody, the vowels and phrases run along on even tones. The speech of an epileptic is, in fact, "plateau speech"; that is, his melody proceeds by even steps. There is also a tendency to monotony; that is, the successive sounds do not vary as much from each other as normal ones do. Both these characteristics are clearly shown in Fig. 7, which gives the melody plot for "mostly by day" spoken by O'Connor. Fig. 8 shows two plateau tones from the word "sleepy" by O'Connor. Fig. 9, by Donohue, "mostly by day," shows melody and plateau tones, although some of the vowels have a little flexibility. Fig. 10, for "four months old," by Coyle, shows both characteristics.

In a list of 100 cases one of us (Clark) was able to detect the disease in 75 per cent. of the cases by the voice sign alone. There is no precisely similar defect in any other nervous or mental disease. All types of epilepsy have been under study. One case had had but four epileptic fits and had never taken medicines for his disease. The voice sign seems to develop with the disease. The more severe the epilepsy and the longer duration it has, the more marked one finds the voice sign.

The sign appears to depend upon the underlying brain degeneration, of which the epileptic fits are also an expression. The voice sign persists at

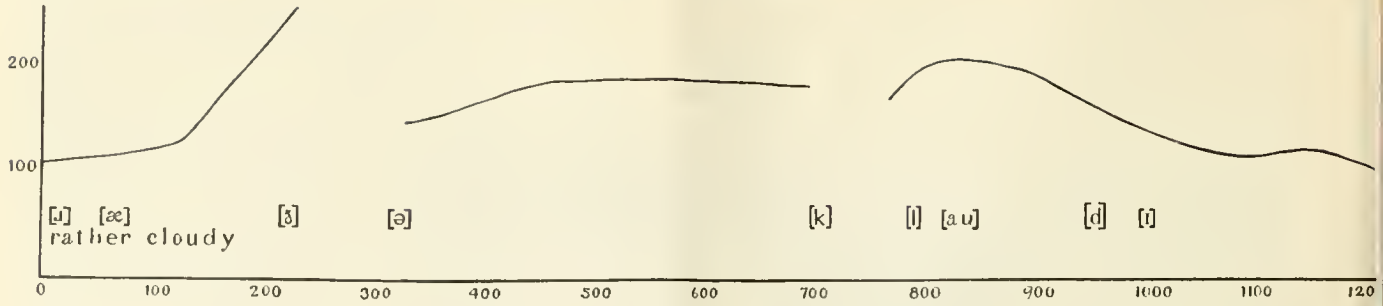

Fig. 4.

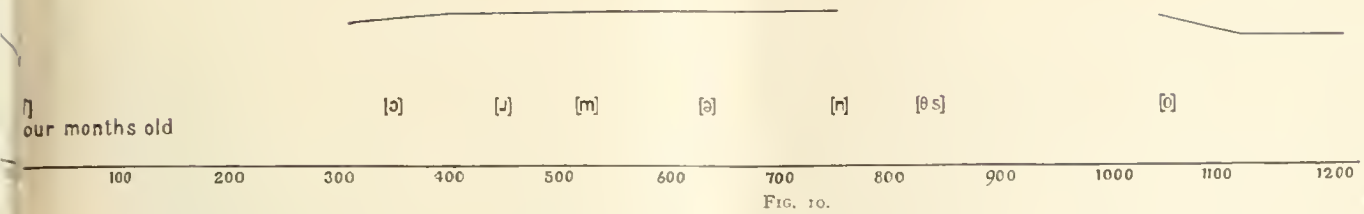

FIG. 10.

least several years, even in the absence of fits, showing perhaps that even a prolonged absence of fits in epilepsy does not really indicate that a cure has been accomplished. The diagnostic and prognostic value of the epileptic voice sign is obvious. Further studies upon the subject are being made.

By appropriate exercises epileptics can learn to speak normally. The voice readily relapses to the epileptic type through negligence, but the cure can be kept complete if the patient will present himself at regular intervals.

NOTES.

1. This research is the first one to appear from the experimental laboratory (in charge of Dr. Scripture) of the Neurological Department of Columbia University, Dr. M. Allen Starr's Service. Part of the work was done in the physiological laboratory (Prof. Curtis) of Columbia University.

2. At a meeting of the N. Y. Neurological Society, April, 1907, Dr. Scripture gave an account of the method employed, and illustrated it by voice records in general paresis. A detailed account of the apparatus and methods of measurement is given by Scripture in Untersuch. über d. Vokale, *Zt. f. Biol.*, 1906.

WHAT FACTORS ARE NECESSARY IN ADDITION TO ASEPSIS TO SECURE HEALING BY PRIMARY UNION?*

By RICHARD WARD WESTBROOK, M.D.,

BROOKLYN, NEW YORK.

ATTENDING SURGEON, BROOKLYN HOSPITAL.

How often does one hear the occasional operator bemoan his inability to get primary union, even with the most elaborate precautions to preserve asepsis? And how often is the sterility of the materials questioned, the possibility of the nurse having failed of her full duty in preparation, the presence of an ungowned spectator as a source of infection, etc.? The explanation is sought in a "break" somewhere in the chain of asepsis. If an operation be done in a private house, in unaccustomed surroundings, there is a considerable possibility of not obtaining complete asepsis. If it be done in a well-ordered operating room, where the advantage of sterilization of dressings under pressure is to be had, as well as the "team work" and facility of a staff accustomed to working together, I believe that any practical break in the asepsis rarely occurs. What is the explanation, therefore, of inability to obtain primary union under conditions which we may be sure are what are ordinarily understood to be completely aseptic? I shall enumerate the several most important factors which I believe to be necessary to secure perfect healing in addition to initial asepsis.

First of all, while I would not be misunderstood as decrying consistent asepsis in the slightest, I believe that much of our aseptic technique is carried to an absurd degree, is often inconsistent in the lacking of one or more essentials, and is made so unwieldy that the other factors which I shall mention are necessarily crowded out. Why was it possible for Lawson Tait to obtain such excellent results without antiseptics and with ordinary tap-water, unfiltered and unsterilized? I think it was, without question, because he was essentially and consistently clean in the first place, and chiefly because he had learned how to handle tissues with a minimum of traumatism; that he knew the limit of toleration of tissues—their resistive power, in other words—and kept safely within this limit. It is to emphasize this latter side of the technique of successful surgery, as distinguished from the former, or aseptic, side that is my endeavor tonight. One might say that it was impossible to have too much of what is included under the term "asepsis," and that is in a general way true. But in another way it is not true. I have seen in a hospital connected with one of our large medical colleges half a dozen people enveloped in caps, gowns, and rubber gloves to do a prostatectomy on a patient with an infected bladder. All this array was unnecessary to secure the desired result in such a case, and yet, of course, it was difficult to depart from the accepted routine, and only goes to show that our regular methods of training physicians and nurses emphasize especially the extrinsic details, so to speak, of aseptic surgery. The intrinsic details pertaining to the handling of the wound itself are too often made to take a very secondary place in the means to obtain primary healing, so weighty and numerous are the other details. When a large incised wound, which has been closed hastily in an emergency on the street or in the woods, where all aseptic externals are lacking, heals by primary union, great surprise is often felt that such a thing can be possible, but the lesson is too little heeded. I was much impressed to see a well-known operator go through his morning's work of five or six laparotomies without a change of the white, short-sleeved coat that he wore, and with only a constant and thorough cleansing of his ungloved hands at the city water tap, the water, however, being known to contain no colon bacilli. This operator's record for primary union is probably equal to that of any. His clean and gentle handling of the tissues, his care in tying ligatures and placing sutures were in constant evidence, and while I believe his methods of asepsis were essentially correct, he was laying more stress upon what I have termed the intrinsic details of his work. Personally, I am a firm believer in the necessity of rubber gloves for the average man; but I am not at all doubtful that the operator who handles tissues with great care may get most excellent results without them, provided he constantly and consistently keeps his hands clean at all hours of the day, using gloves when under the necessity of handling pus. I am persuaded, there-

*Read before the Long Island Medical Society, June 2, 1908.

fore, that we need to emphasize in the training of internes certain of these intrinsic essentials, even if we crowd aside some of the accepted extrinsic essentials.

First of all, when an incision is being made, we should avoid all unnecessary clamping of bleeding points. Capillary oozing and bleeding from small vessels do not require clamping, and soon cease spontaneously. The energetic interne often spends time and obstructs the operator in putting artery clamps unnecessarily upon such points, feeling that the assistant who can snap the largest number of clamps on in a given time is doing greatest service to the operator. On the contrary, and more important still, it inflicts added traumatism, and requires the leaving of a greater amount of ligature material in the wound for the tissues to care for.

The next important matter is that all bleeding points should be seized neatly and exactly, and no large masses of tissue clamped off to undergo necrosis later, and tax the phagocytic power of the tissues. Vessels may often be seized before being cut through, but the two clamps upon a vein crossing the incision should be placed close together, not at a distance apart, as the knife can easily sever between them, and a smaller stump will be left to be ligated. It should always be kept well in mind that the ability of any wound to care successfully for dead aseptic material left within it is limited, and the less necrotic material left the greater the chances of primary union. I think it important, so far as possible, to avoid leaving considerable masses of crushed and strangulated tissue immediately beneath the skin, as such tissue is more prone to become infected from the neighboring organisms within the deeper skin-layers. As an artery clamp, I prefer the pattern of Kocher, with a sharp, toothed point by which a vessel may be accurately seized and crushed. Often no ligature is required after the use of such a clamp on small vessels, although I prefer as a rule to ligate nearly all points clamped, and to clamp few points.

The tying of the ligature is a point of great importance. The majority of men will tie off the tissues at a distance from the point of the clamp, and thus strangulate surrounding fat and fascia to a much greater degree than if the ligature be given its first tie on the tip of the clamp, and allowed to slip over the clamp upon the extreme end of the tissue caught as this first tie is tightened. The ligature should be trimmed off short for all ordinary vessels, though for arteries of considerable size three ties of the catgut ligature should be taken and the ends left a little longer. For superficial veins and arteries, I frequently use but one tie of the catgut, a half-knot, clipping the ends very short, and if it be drawn up very steadily and firmly it will not slip off. Catgut is dead animal tissue rendered aseptic, and the amount of it left in the wound should in every way be reduced to a minimum. I have long noticed the great difference in the amount of dead material left to the care of the wound where the points I have mentioned in the clamping, the tying, and the cutting of the ends of the catgut were carefully observed. Of course, no wound can be more than relatively aseptic, as absolute asepsis is not practicable, and the more dead or devitalized material left in a wound the more easily is bacterial development made possible.

Another important point lies in the proper sponging of the wound. A common habit of inexperienced assistants is the wiping of a rough gauze sponge across a wound, very much as one would rub off the external skin. Such practice produces trauma of the superficial layers of the delicate tissues of the wound, and devitalizes them to a certain degree. A sponge should be laid gently and firmly against the exposed tissues and quickly removed, without any rubbing or scrubbing.

Irrigating fluids should be used as little as possible. Aseptic surgery presupposes that no corrosive antiseptics be washed over tissue surfaces to injure them, but saline irrigations are also unnecessary, and, with the additional sponging required, only add to the handling of the tissues. Blood has bactercidal properties in itself, and there is no necessity of removing it when not in considerable amount.

The tying of sutures so as to avoid tension on tissues is one of the most important of the points I have to mention. Tension is invariably harmful whenever used, and is always done at the risk of inducing suppuration. A moderate tension is required in suturing the muscle to Poupart's ligament in a radical operation for inguinal hernia, and tension is necessary in closing large gaps, as in operating for large umbilical hernia. But all such tension must be reduced to a minimum, for with tension there is surely constriction and necrosis of tissues, and the production of a favorable culture medium for any accidental infection. It is useless to attempt impossibilities with tissues, and the efforts one often sees made to drag tissues to distant areas at the expense of their blood supply are foolish in the extreme. Buried sutures of absorbable material should be tied with little tension, as well as superficial and skin sutures, in order to make provision for the resulting edema which follows, adding to the tension and the dangers of necrosis. The areas of irritation and suppuration seen about skin sutures are not so much due to the mere presence of germ-life in the skin as to the fact of tension and necrosis rendering germ activity possible. Skin may be brought into good coaptation by loose but even suturing, the atmospheric pressure assisting in holding the lips of the wound together, combined with firm, even pressure of dressings. Personally, I seldom use a subcuticular suture, as I believe the dangers of skin infection are only theoretical if tension of the skin sutures be avoided. As a rule, I think that a wound may be more evenly sutured with an interrupted skin suture of fine silk or horsehair, and that such a suture permits of an escape of serum from the lips of the wound, which is often an advantage. The subcuticular suture does not prevent a scar, as one usually finds as much scar formation in after months with them as with wounds sutured otherwise, except that the scar-points of the needle holes are lacking.

It is not my intention in a paper of this length to cover my subject exhaustively. It is necessary to say that I consider rubber gloves, caps, and masks essential in every operation where asepsis is to be maintained. There is no known means to render the human skin aseptic, and therefore the use of gloves, with all their alleged dangers, brings one nearer the aspetic ideal. One accustomed to gloves can use them safely and to great advantage. That an effective mask should be worn I consider most essential. The human mouth is a veritable breeding-ground for germs of all kinds, including virulent pus-forming organisms. I have presumed in the consideration of my subject that these essentials of asepsis are made use of, and it is the discussion of factors apart from asepsis that are necessary to the obtaining of primary union to which I

am limited. There is one factor which it is difficult to discuss strictly from the standpoint I have chosen, and that is catgut. Whether catgut as prepared by the many methods in vogue is truly aseptic I cannot say. Doubt has been expressed by some as to whether it is possible to sterilize catgut at all, so as to maintain its tensile strength and its other necessary physical properties. However that may be, it would seem from surgical experience that catgut subjected to a sufficiently high degree of heat for a sufficient length of time may be rendered aseptic, and any spores it may contain be destroyed. Catgut prepared with chemicals without heat is said to be found lacking in complete sterilization, the chemical antiseptics not penetrating to the center of the strand, permitting spores to remain there alive. If this be actually the case, it would seem from the very large and successful experience of surgeons with bichloride-alcohol gut, iodine gut, iodoform gut, and silverized gut, that the antiseptic penetrating the outer layers of the gut is sufficient to prevent the development of spores as the gut disintegrates in the tissues. Spores will not develop from such gut in culture media incubated for long periods in the laboratory, unless in some manner the antiseptic be removed or neutralized. It is my personal opinion that the results obtained with the standard preparations of catgut vary with the technique of the operator more than with the method of preparation. Operators have reported long series of good results with preparations of gut which, without question, have not been sterile, and surgeons have even been known to use unprepared and unsterilized catgut with resulting primary union. But no chance should be taken with catgut which has not been prepared by a method which experience has shown to be completely protective against tetanus, the greatest of all the dangers which may lurk in catgut. My own experience with iodine catgut prepared by the method of Claudius, with the modification of using it dry, as suggested by Moschowitz, has been all that could be desired. In a long series of operations I have failed in no instance to obtain primary union where there was not a well-explained cause for not obtaining it, which had been anticipated. My experience fully verifies the claims of Moschowitz that it is absolutely sterile, difficult to infect, does not act as an irritant upon the tissues, and that it is so easily prepared that only gross carelessness or ignorance would permit gut prepared by this method to be otherwise than safe. While my experience with iodine gut prejudices me in favor of an antiseptic catgut, I may say also that I believe a careful observance of the suggestions which I have laid down in this paper will produce equally good results with aseptic gut, or antiseptic gut prepared by other methods. Iodine gut does not retain its tensile strength indefinitely, and should be used within a month or six weeks. In my hospital work I have used only the iodine gut, and an antiseptic chromic gut prepared with bichloride of mercury and alcohol. In my outside operations I have had essentially the same good results with an aseptic gut prepared by one of our best known producers. In no instance have I used a gut larger than No. 2 in size, and as a rule for ligatures I have used No. 0 and No. 1. Fine sizes of catgut, like fine horsehair may be used only by those operators who cultivate a firm and steady tension in making the tie. There are few strands of catgut of these sizes that cannot be broken with an abrupt pull, and especially in attempting to make the second tie of the knot too tight. But fine sizes of good catgut have large tensile strength if the pull be a steady one. If for any reason I prefer a heavier or stronger ligature than No. 2 gut, I use the gut double, its absorption being more ready in the tissues with less likelihood of irritation than if a larger strand be used. The matter of sizes is important, as different makers number the gut differently. One should become accustomed to use certain sizes for certain parts of his work, and see to it that these sizes do not vary. Only by routine accuracy in such matters can the same results be uniformly obtained. It is my custom in all important ligatures to make a third tie upon the knot, as I have known ligatures and sutures to untie after the gut had become swollen in the fluids of the tissues. This practice with small catgut has never given me any trouble.

Next to the suggestion of the use of antiseptics by Lister, nothing in the technique of surgery has been so important as that second suggestion by the same great surgeon, of catgut as an absorbable ligature. Wherever possible, catgut should take the place of nonabsorbable ligatures and sutures when buried in the tissues. Correct methods of the use of catgut are worthy of the most thorough study.

With improved technique and facilities, it has been only rarely my experience in recent years to meet with cases of such lowered resistive power that clean wounds would not heal by primary union. That such cases exist there is no question, but care in the handling of tissues reduces their apparent numbers greatly.

In considering my subject with you this evening I have told you nothing new, but have brought up a few points which I think need occasional discussion. It is greatly to be regretted that there is such lack of uniformity in our hospital methods throughout the country, and that the pursuit of new methods and fancies often obscures the everyday essentials which are absolutely necessary whatever be the methods used. It is essential that the body tissues be always treated with a gentle hand, whether in the taxis to reduce a hernia, in the dressing of a wound, or in the course of an ordinary operation. If tissues be treated roughly, harm of one kind or another will result, which no amount of antiseptic or aseptic form will offset.

1145 Dean Street.

PRELIMINARY NOTES UPON A CASE OF LEPROSY APPARENTLY CURED WITH THE X-RAYS.

By VICTOR G. HEISER, M.D.

PASSED ASSISTANT SURGEON, P. H. AND M.-H. S.; DIRECTOR OF HEALTH AND CHIEF QUARANTINE OFFICER FOR THE PHILIPPINE ISLANDS.

The patient in question was admitted to the San Lazaro Leper Hospital, Manila, P. I., August 12, 1906, with the following history:

Leon Liuanag, male, aged 20; unmarried; Filipino; laborer; uses tobacco moderately; uses no alcohol; good habits; present residence, No. 28, Calle Alejandro VI, Sampaloc, Manila.

The parents are alive; the father is in the provinces, suspected of having leprosy; mother is well; has one brother, alive and healthy; no sisters.

The patient has had no previous diseases of importance; venereal history is negative.

Two years ago he noticed a swelling on the upper lobe of the right ear. This swelling was reddish in color, not itchy nor painful. He treated it with family remedies, but it continued to grow worse, spreading all over the ear. Three months after the

first lesion appeared on his right ear, he noticed also a macular lesion on his lower lip, reddish in color, not anesthetic, not itchy nor painful, which continued to grow slowly. He made no attempt to treat this second lesion. He says that he had had no other symptoms since the appearance of the disease.

Physical Examination.—1. General. Development and nourishment, fair; reflexes, negative; glands, negative; genitals, normal.

2. Head. Scalp, normal; eyes, negative; above left eyebrow there is a small round tubercle, reddish in color, but not anesthetic, not itchy nor painful; nose—the tip shows a reddening, and it is shiny in appearance, and the alaenasi are infiltrated; mouth—the border of the lower lip shows from the middle portion to the right angle, a macular lesion, red in color, not anesthetic, not itchy nor painful, but with slight infiltration, and measures about two cm. by 6 mm.; ears—left, normal and about 4 cm. in length; the right ear is hypertrophied and measures 7.5 cm. in length, and about 4 cm. in width; reddish brown in color, and its lobules show some breaking down of the tissues with some suppuration; outer portions of eyebrows very thin; rest of face, normal; neck, normal.

3. Chest. Skin, normal, except that the back shows several round white spots which are somewhat anesthetic; development and expansion, good; heart, normal; lungs, normal.

4. Abdomen. Skin, normal; organs, normal.

5. Extremities. All are normal.

On September 27, 1906, he presented the appearance shown in Figure 1.

Treatment was begun November 5, 1906, from which date the lesions on his head were exposed every three days to *x*-rays for ten minutes at

Fig. 7.—Before treatment.

a distance of 25 centimeters from the tube. The intensity of the light employed was just sufficient to give a distinct outline of the bones of the hand. The regular Gundlach tube and a 45 cm. spark induction coil and a mercury turbine interrupter were used. From November 21 to January 21 the treatment was the same with the exception that his head was placed within 18 cm. of the tube. During this period he commenced to show considerable improvement, in that the lesions, most noticeable in the right ear, were rapidly growing smaller. From January 21 to February 8, 1907, he was exposed at a distance

Fig. 2.—Showing results of treatment.

of 12 cm. from the tube. From February 8 to February 26, he was exposed every two days at a distance of 12 cm. From February 26, 1907, to July 1, 1908, every two days at a distance of 25 cm. for ten minutes.

During June, 1907, the affected parts presented almost a normal appearance. The lepra bacillus was difficult to demonstrate and many specimens were often necessary in order to find it. During January, 1908, the case was apparently cured from a general clinical standpoint, the infiltrations had entirely disappeared, there were no anesthetic areas, the ears were normal in size, and the cosmetic effect was practically perfect, so far as the leprosy was concerned. No lepra bacilli could be demonstrated at the site of the leprous lesions at which they had heretofore been found, but *they could be found in scrapings made from the nasal septum.* Shortly before this period, yaws made its appearance among the inmates of the Leper Hospital, and he also contracted this disease soon afterwards.

Between January and June, 1908, repeated microscopic examinations were made, and lepra bacilli could be found only in specimens taken from the septum of the nose, and during the latter part of this period, it became more and more difficult to find them even there. From June 15, 1908, to August 1, 1908, the date of the last observation, it has been impossible to find lepra bacilli in specimens taken from any portion of his body, and he presents the appearance shown in Figure 2.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, October 31, 1908.

RECENT PROGRESS IN OUR KNOWLEDGE OF SYPHILIS

THE discovery of *Spirochæta pallida* by Schaudinn and Hoffmann and the application of serological reactions to the diagnosis of syphilis by Wassermann have rapidly placed this disease among such affections as are capable of being studied by the experimental methods that have been so productive of results in other infectious diseases. However uncertain is the precise rôle of the spirochete in the causation of syphilis—uncertain, because the requirements of the Koch circuit have not yet been completely fulfilled so far as the growth of the organism outside of the animal body is concerned—the results of animal experiments have shown without any doubt that secretions containing the organism are capable of producing syphilis in apes, and localized specific lesions in rabbits and other animals. The one possibility, namely, that the spirochete is a symbiotic organism simply accompanying the real excitant of the disease that has so far escaped detection, is of course to be kept in mind, but the value of the demonstration of the spirochete in the clinical and experimental lesions of the disease is not lessened by the existence of this possibility.

Wassermann's reaction, on the other hand, is quite independent of one or the other excitant of the disease: it depends upon the use of the extracts of organs of syphilitic fetuses, and the presence of the toxins of the disease in such extracts is of course admitted whatever may be the final source of them. That the reaction possesses a value far beyond the mere diagnosis of individual cases of acquired syphilis is shown by J. Bauer in the *Wiener klinische Wochenschrift* for September 3, 1908. Bauer tried the reaction in over two hundred newborn children and obtained a positive result in twenty-two cases. Not only every clinically diagnosable case of inherited syphilis gave a positive reaction, but many doubtful cases were proved to be syphilitic by the result of the test. The importance of these results can hardly be overestimated: they mean, on the one hand, that a positive diagnosis of inherited syphilis may be had in every case where doubt had previously existed and, therefore, treatment may be early instituted; on the other, that two great sources of syphilis insontium, the infected wetnurse and the syphilitic baby, may be early recognized and properly guarded against.

Bauer tested as far as possible the parents of the syphilitic children for the presence of the disease and the results were highly interesting, throwing light as they do upon the well-known phenomena of immunity to syphilis in the mother of a syphilitic child and in the children born of syphilitic parents but who have not inherited the disease—phenomena noted by Colles and by Profeta and often known by their names. The mothers of syphilitic children gave positive reaction for the disease even though clinically they were quite free of all signs and symptoms of it: the fact of Colles' law seems to depend, therefore, upon the presence of latent syphilis in the mother. The same cause explained the seeming immunity of children to infection with syphilis, the presence of the disease in them being shown by the positive reaction for the specific antibodies of syphilis though clinically they too seemed to be free of the disease.

These data afford evidence of the great impetus given to the study of syphilis by the work of Schaudinn, Hoffmann, Wassermann, and many others. Early diagnosis means early treatment and, in many cases, the prevention of the spread of the disease. It is quite possible, too, that the ability to study the disease in animals may result in the discovery of more effective or at least more rapid methods of cure than the use of mercury and the iodides, whether such cures depend upon newly discovered drugs or the preparation of antitoxic sera. The loss of life, health, and happiness, to say nothing of the great economic losses, suffered by mankind because of this protean disease is so appalling that all possible encouragement and help ought to be given to the workers employed in the task of discovering new means of recognizing and fighting syphilitic infection. It is therefore much to be regretted that the general public is not as educated in regard to the nature of this disease as its importance demands, and that many of the medical profession look upon it merely as a venereal affection which is a fit sequel of the debauches of the criminal and the unprincipled. It must ever be remembered that not a small number of the syphilitic patients have acquired the disease innocently, that innocent wives are often infected by their husbands, and that inherited syphilis strikes down or cripples innocent children. Syphilis, like tuberculosis, is a great plague of mankind, and it is the duty of the profession not only to search for the best means of recognizing and treating the disease, but also to educate the public in its individual and social prophylaxis, and in the means of preventing its spread, so that results similar to the striking effects of such education in the case of tuberculosis may be speedily attained.

THE RIGHTS OF THE SANE.

MENTAL aberration is enormously on the increase in all civilized countries. Perhaps the chief cause is the love for urban life which distinguishes the present generation both in America and in Europe. Living in towns undoubtedly changes an individual's characteristics, and will, in time, change the type of the human product. In no country has this fact been more clearly demonstrated than in Great Britain, where the type of man has altered almost beyond belief within the past fifty years and is still altering. In place of the phlegmatic undemonstrative self-reliant Briton of the old days, different conditions of living have evolved the present-time

high-strung, nervous, almost hysterical, inhabitant of British towns. Insanity has certainly increased in America and in Great Britain *pari passu* with the congregation of great masses in the towns, living at high pressure in regard to business and amusement. The future generation of civilized beings tends fair to be more prone to mental disorders than the preceding, as its members will have inherited various nervous traits in an exaggerated form. A writer of some note predicted a short time ago that if affairs progressed at the rate they had been progressing recently, the insane in England would outnumber the sane, and Lord Roseberry but a few weeks ago pleaded that the insane should not be permitted to be an affliction and a danger to the sane.

There are said to be many in Great Britain who act on the principle that the world is made for the inefficient, the sickly, the foolish, and the mad, and that taxpayers and workers should be considered only after the interests of semi-lunatics and the unfit have been attended to. Matters may not be so bad as this, but it is obvious that affections of the nervous system and madness have developed to an alarming degree within recent years. How often does one hear that a prominent business or public man has broken down and has to be recuperated by the rest cure or the primitive life cure, or some similar method?

Our courts of law are not infrequently employed in trying the cases of rich degenerates who have broken the laws of the country, and who in a less sentimental age would have been given but short shrift, but to whom now is extended pity unbounded; and, as a rule, they get off scot free. To observe the audiences also when such a case is being tried is sufficient proof that degeneracy is prevalent. Indeed, there is no need whatever to heap up facts to show that mental instability is a feature of the times, the magnificent buildings for the reception of the insane in New York State alone would be proof enough.

Given, then, that insanity is prevalent and that nervous complaints of every description are more than prevalent, is it true that in America, as well as in Europe, too much consideration is paid to the unfit, and that the sane have to suffer for the insane? No one would argue that we ought to revert to the custom of times long past, when the doctrine of the survival of the fittest was in practical application, but it is, at any rate, a matter open to doubt if we are not coddling the useless too much nowadays. It is quite right that the sick and helpless should be aided, but there is a limit to such assistance, and it is by no means certain that we are not going too far in the other direction. The strong and self-reliant are those who will win in the long run, and to teach the masses to be slack and placid is to court disaster.

In this country the infusion of the blood of strong and healthy stocks from Europe has kept the balance up to the present time fairly well, but unfortunately now the character of immigration has greatly changed. Instead of the strong, sturdy Scandinavian and German, the country is being flooded with far less desirable races, some of whom are parasitical in tendency, who never get further than a large town, and who help to swell the mass of mental, physical, and moral incapables abounding in these places. So long as the class of immigration is what it is, so long will degeneracy and mental disorders flourish. America, as well as Europe, has her problem of insanity to solve, and she may find that it is not the wisest way to meet it by treating the sufferers from nervous complaints with too much consideration and deference.

THE FOREST FIRES.

It is difficult for one who has not been through the Adirondack region recently to conceive of the barren waste which large areas now present as a result of the devastating fires. In two whole townships of Franklin County there is hardly a stick of live timber standing. The entire region is full of smoke. Homes, institutions, camps and property of all kinds have had a narrow escape. Some dwellings have been burned, but fortunately there has been no loss of life so far as known. It is hoped that out of the recent experiences, ultimate good will come. It is useless for the State to establish forest preserves and then allow them to be burned up by the careless railroads. The latter are now hard at work but they have been too late. As long as coal-burning locomotives are permitted to run through the forests just so long we shall have fires. To substitute electricity would be impracticable, but it is perfectly feasible to use oil-burning engines. In fact one branch of the principal line through the woods is so managed now and it has had a practical immunity from fires. The Public Service Commission has recently made an inspection of the fire district and doubtless measures of relief will be brought before the Legislature next year. This State originally had a grand endowment in the way of forests and if they are to continue to serve as a place for regaining health and energy it is high time that something be done to care for those which remain. It is useless for the railroads to throw the blame on careless campers. That the latter are entirely guiltless no one would assert, but the former are the sinners in nine cases out of ten. Many fires breaking out a long distance from their tracks have been started by them originally, for burning brands are blown sometimes for miles and thus a new series of fires is started.

It is poor policy to send patients to the Adirondacks if they are to be blinded with smoke, which also irritates their throats, and when all they can see are large blackened areas which make "mountain scenery" a mockery. It is for the interests of the railroads themselves to conserve the woods. So also the lumber companies should be prevented from leaving the waste products of their cuttings—the "slash," as it is called—to rot on the ground and add just so much inflammable material to a possible fire. Every physician, every mountain visitor, and every lover of nature should bring to bear all possible influence upon those in charge of legislation so that wasteful and dangerous methods of managing our forests should cease. At present we are feebly striving with effects instead of removing the causes. The experience of the general government has shown that constant patrol is the only efficient remedy against fires. The present warden system is too slow in getting into action in case of a

large fire. As it is now in the Adirondacks, no one pays any attention to a fire until it gets under a great headway. Private owners can look out for their preserves but the State should be equally provident with its own acres.

Tuberculin Reaction and the Nervous System.

The wide popularity which the recently introduced local reactions to tuberculin have enjoyed has led to renewed attempts to explain the general nature of the effect exercised by tuberculin upon the skin of tuberculous patients. Thus v. Pirquet has written very convincingly in defending his view of the matter according to which the phenomena of the tuberculin reaction are caused by the interaction of the toxins in the preparation and the antibodies developed in the organism during the disease. But a number of very interesting observations reported in the *Münchener medizinische Wochenschrift* for September 29, 1908, by Moro, who introduced the "percutaneous" reaction to tuberculin into practice, seem to require other explanations than that proposed by v. Pirquet. Thus in several of Moro's cases after the inunction of some tuberculin ointment into the skin the specific reaction to tuberculin appeared not upon the site of application but upon the corresponding area of integument on the opposite side of the body. Several other patients, in addition to the typical local reaction, showed a disseminated eruption elsewhere on the skin. Still others presented girdle-like eruptions reaching across to the middle line of the body, very similar in appearance to the well known eruption of herpes zoster. Inunction of plain lanolin led to the appearance of the reaction on the skin thus treated, if at the same time another spot was rubbed with the tuberculin ointment. In general, these and similar observations lead Moro to conclude that the nervous system plays an important rôle in the appearance of local tuberculin reactions; the latter are vasomotor phenomena, the nervous system of the tuberculous subjects being oversensitive in a certain specific manner to the action of tuberculin. The appearance of the reaction upon corresponding areas of the skin leads him to conclude that the spinal cord is affected by the stimulus applied at the site of inunction and sends out stimuli along the efferent nerves from the centers affected. That the antibodies of the organism may also take a part in the production of the reactions is, of course, not excluded by the above observations; but that the sympathetic nervous system is involved seems very probable.

Direct Contagion of Typhoid Fever.

In the issue of the *Journal de Médecine de Bordeaux*, for September 20, 1908, attention is called to man as a carrier of typhoid infection. In our consideration of water-borne typhoid and our zeal to purify the water supply we have in a measure lost sight of a number of ways in which this disease may be carried about. Auché says that the curve of water-borne typhoid is peculiar. After a few oscillations there is a quick fastigium. The germs appear only in a transitory way in the water and may not be found when it is examined. Thus there is not a continued increase of infection and the severity of the disease is lessened. Koch thinks that outside the body the germ of typhoid is short lived, especially in water, and man is regarded as the principal carrier of the disease. In epidemics carried in this way the course of the disease is long and the elevation of temperature comparatively low. The patient who is confined to his bed is only slightly dangerous since his discharges may be disinfected. It is the person in the incubation stage of the disease who has already the germs in his intestine who distributes them about. Again in the stage of convalescence the bacilli are still present in the feces and in the urine. Cured patients may carry the germs in their intestines for an indefinite period. Still another class of fever distributors are those who come in contact with the sick and are not affected by the disease, yet carry the germs in their feces. In the patient who is sick the germs are present in the pharynx and mouth, and in the blood. Kissing the patient, or using the same dishes that he has used may transmit the disease. The frequency of chronic carriers of the bacillus is considerable. In these cases the germs are generally carried in the gall-bladder, and there are intermittent attacks of intestinal trouble. Out of 1,700 persons who had never had typhoid fever Klinger found eleven who showed the germs in the intestine. Kayser found twenty-seven out of 1,800 persons. In these persons the bacilli remain in a saprophytic condition. All these facts show how much more difficult is the struggle against the infection of this disease than we have hitherto supposed, and how much more thorough and broad must be the measures taken against it.

News of the Week.

The International Association of Medical Museums held its second meeting in Washington on October 1 and 2, in connection with the International Congress of Tuberculosis. Prof. W. G. MacCallum of Baltimore was elected President to fill the vacancy caused by the death of Dr. James Carroll, the first President of the Association. Dr. Maude E. Abbott of McGill University, Montreal, was elected Secretary. The executive session was occupied by discussions of the function and scope of the Association and the desirability of closer affiliation with the Museums Association of Great Britain and the American Association of Museums. There were many arguments brought forward to show the advantages of such affiliation, but it was felt that the time was not yet ripe for such action. The issue of a Museum Bulletin was discussed, to serve as a pathological clearing house by which scientists could be informed of specimens available for exchange. It was voted that an editorial committee of five members, to include the President and Secretary, be appointed to edit and publish a Bulletin. The question of establishing an Index Pathologicus was also discussed, and was referred to the Executive Committee.

Dr. W. G. MacCallum read a paper on the Preservation of the Results of Research as Material for Medical Museums. He laid especial stress on the systematic preservation of the results of any given piece of research so that they might remain intact as objects of study for any one engaged in a collateral piece of work.

Dr. Maude E. Abbott spoke on the Classification of Museum Specimens. She felt that the Dewey decimal system, which had been employed for some nine years in the McGill Medical Museum, was extremely satisfactory. The advantage of the system was that it supplied a descriptive group number, so that any one specimen might be added at any time without disturbing the sequence of the

consecutive numbers. The figures representing the anatomical classification preceded, those of the pathological classification followed, the decimal point, while the individual specimen was indicated by a small index figure placed at the upper right hand corner of the descriptive number; thus 11.34[1]. Dr. Lamb said that simplicity was the chief thing to be aimed at in cataloguing specimens, and Prof. A. S. Warthin spoke of the difficulty of satisfactory classification because of differences of opinion which exist on theories of disease. Dr. Abbott, in closng the discussion said that the chief point in avoiding complications was not to attempt too minute a subdivision of series, but to use the numbers merely as a key to the systematic arrangement of large masses of material.

Dr. E. Souchon of New Orleans demonstrated anatomical preparations prepared by a method published in the *Journal of the American Medical Association*, August 22, 1908. Dr. Watters of Boston demonstrated the different steps in his method of mounting museum specimens in gelatin (MEDICAL RECORD, December 22, 1906). Dr. J. G. Adami of McGill University, Montreal, read a paper by Mr. E. L. Judah on methods of mounting moist specimens in square glass jars, on frames, and under clock glass, etc., the chief purpose of the demonstration being to show some of the finer practical points in the technique. Mr. F. Izzard of Cambridge, England, described a rapid method of macerating bone, by which the process of bleaching is completed in a very short time. Dr. A. S. Warthin demonstrated a new square museum jar which, by the use of sheet rubber and a wooden clamp frame, might be closed without the use of cement. Dr. Maude E. Abbott demonstrated a series of specimens of anomalies of the heart from the Army Medical Museum, and the museums of McGill University and the Johns Hopkins Hospital.

Protection of State Charitable Institutions Against Typhoid Bacilli Carriers.—The New York State Board of Charities has adopted a suggestion to the State charitable institutions under its supervision that they retain in quarantine inmates who have recovered from typhoid fever until bacteriological examinations demonstrate that they are no longer carriers of the typhoid germ. It also suggests that attendants who have recovered from typhoid fever shall not return to duty until they are certified by a competent bacteriologist to be free from the bacilli of that disease.

Stonywold Sanatorium Threatened.—The forest fires in the Adirondacks have caused a great deal of damage this fall, and last week reached almost to the buildings of the Stonywold Sanatorium near Lake Kushaqua. A call for help was sent to Utica, and a number of firemen were dispatched to aid the fire fighters at the sanatorium. Their combined efforts, aided by the dying down of the stiff wind which had been blowing, finally resulted in beating the flames back. In the meantime preparations had been made to remove the patients if necessary and a train of cars and engine was in waiting at a siding.

Bubonic Plague Stamped Out in San Francisco.—Because of the greatly improved conditions in San Francisco, orders have been sent from the office of the Surgeon-General of the Marine-Hospital Service to discontinue the disinfection of vessels leaving that port. For more than a year all outgoing vessels have been fumigated for the purpose of killing rats to prevent their conveying the plague to other ports, domestic and foreign. There has now, however, been no death from plague in the city for eight months. Numbers of rats have been trapped or killed and examined each week, and but two showing infection have been found since July 13. Since August none has been found.

Cholera on United States Transport.—A private soldier is reported to have died of cholera on the United States transport *Buford* during her voyage from Manila to Nagaski, at which latter port she has been detained. There are said to be other cases on board. The situation in Manila in regard to the disease is so far improved that the sailors of the visiting fleet are to be given shore leave.

Tuberculosis.—The Commercial Club of Chicago, with that public spirit which has actuated it in so many movements looking to the betterment of the citizens of Chicago, is taking an active part in the effort to eradicate or minimize tuberculosis in this city. The members of the club are requesting special inspection service, and whenever necessary will put their places of business in proper sanitary condition. The club also recommends that its members contribute as their means may afford to the splendid work of the Chicago Tuberculosis Institute.

Death Rate in New York.—For the week ending October 17, the death rate in the entire city was 14.39 per thousand, as compared to 16.43 for the same week in 1907. The total number of deaths was 1,220 for this week in 1908, and 1,350 in 1907. There were 23 deaths from typhoid fever, an increase of 6 over last year, and 88 deaths from violence, an increase of 7. Among children under one year of age, there were 287 deaths in 1907, and 278 in 1908; under five years, 447 deaths in 1907, and 383 in 1908. In the tenement houses there were 594 deaths in 1907, and 521 in 1908.

Christian Science Death.—Coroner Van Patten is investigating the circumstances surrounding the death of a twelve-year-old child of Mount Vernon, N. Y., on October 20, of typhoid fever, after she had been treated for eleven days by Christian Science "healers." A physician was called in the day before the child died.

Race Suicide in France.—The depopulation of France is proceeding at an amazing rate. The vital statistics for last year show a reduction in the birth rate even below the figures of 1906, with an increase in deaths. There were 32,878 less births in the entire country in 1907 than in the preceding year, and 13,693 more deaths. There was an excess of 19,920 deaths over births. In 1906 the ratio of births was 215 to 10,000 of population; in 1907 it fell to 207. The falling-off took place in eighty-two departments, while five showed a slight increase. The decline of births in the outlying rustic regions is most alarming. The excess of deaths occurred in fifty-five Departments, that in the Seine, which is practically Paris, being the largest. From 1901 to 1905, inclusive, the population of France showed an average increase of eighteen a year for each 10,000 inhabitants. In 1906, this dropped to seven; and last year it changed to a decrease of five in 10,000. This is race suicide with a vengeance.

Dr. William T. Bull of New York has been seriously ill for some months and his condition has caused great anxiety. Recently he was moved from his home to the sixteenth floor of the Hotel Plaza, where he could obtain quiet and better air, and a slight improvement in his condition has been noticed.

Dr. William Osler, candidate for the Lord Rectorship of Edinburgh University, was defeated at

the election which took place on October 24, Mr. George Wyndham, M. P., receiving 826 votes to Dr. Osler's 614. Mr. Winston Churchill was also an unsuccessful candidate, receiving 727 votes.

Removals.—Dr. R. J. E. Scott has removed to 107 West Seventy-eighth street. Dr. Carlos MacDonald has removed to 15 East Forty-eighth street.

St. Luke's Hospital Election.—The fiftieth annual meeting of the Board of Managers of St. Luke's Hospital was held on October 21. Mr. George Macculloch Miller was re-elected president of the Board. The report acknowledged the receipt of legacies and gifts during the year amounting to $281,552.

Boston Floating Hospital.—During the past summer the Boston Floating Hospital, with a staff of sixty nurses and seventeen doctors, gave 18,648 days' service to their beneficiaries. Two classes of patients were treated. Those who spent their time continuously at the hospital received 7,116 full days' service of twenty-four hours each. The other class of patients go on board early in the morning and spend the day, and these received 5,440 days' service, while the mothers accompanying them amounted to an aggregate of 5,381, each being fed and cared for during the day. Well children too small to be left at home in cases where mothers came with sick children numbered 711. Over 90,000 separate nursing bottles of carefully prepared and modified milk and liquid food were furnished by the laboratory.

Chicago Hospitals to Merge.—An amalgamation of three south and west side hospitals, Chicago, has just been effected. The Central Hospital Association is the name under which the new régime is to be brought about. This Association has acquired control of the Central Hospital, the Woman's Hospital, and the Illinois Hospital. It is proposed to increase the capacity of these hospitals at once by the erection of a new wing at the Woman's Hospital, together with a nurses' home at the same location. The officers of the Central Hospital Association are: Dr. Beacon, *President;* Dr. J. S. Burkholder, *Vice-President;* and Dr. Fred M. Doyle, *Secretary*. Dr. Stuart Johnstone and Dr. George G. Hinn are members of the Board of Directors. The staff of physicians and surgeons for the associated hospitals is now in process of formation.

St. Luke's Annex Dedicated.—The new $600,000 addition to St. Luke's Hospital, Chicago, known as the George Smith Memorial, was dedicated recently by the Right Reverend P. Anderson, Bishop of the Protestant Episcopal Church. Later there was a reception for the surgeons and physicians connected with the hospital, as well as one for the medical profession of Chicago.

The McKinley residence in Canton, Ohio, has been opened to the public under the name of the Mercy Hospital. It is under the charge of Sisters of Charity, will accommodate about thirty patients, and has been completely equipped by donations from the people of the town.

Examination of Internes for the City Hospital.—There will be an examination of candidates for the position of Interne of the City Hospital of New York on November 7, at 1:30 P.M., at the hospital, Blackwell's Island. Further information may be obtained from the chairman of the executive committee, Dr. Joseph Collins, 37 West Fifty-fourth street.

Ether Day Celebration.—The sixty-second anniversary of the first administration of ether for surgical purposes was celebrated at the Massachusetts General Hospital on October 16. During the morning clinics were held and demonstrations given in the amphitheater. At the afternoon exercises Dr. William H. Welch of Baltimore delivered an address on "Surgery as Affected by Ether Administration."

Swindler Arrested.—A man believed by the police to be one known to them as the "fake radium cure man," was arrested in New York last week, and charged with having perpetrated a swindling scheme through the mails. The complaint charges that he represented himself in circular letters as a celebrated London specialist, and in that rôle succeeded in duping a large number of sick persons throughout the country. The "radium cure man" is said to have already served fourteen months in Joliet prison, eighteen months in an English prison, and eight months in the New York penitentiary on similar charges, in the last case for extorting nearly $10,000 from a patient for alleged radium treatment.

Medical Association of the Southwest.—At the third annual meeting of this Association, held at Kansas City, Mo., October 19-21, the following officers were elected: *President,* Dr. Jabez N. Jackson of Kansas City, Mo.; *Vice-Presidents,* from Arkansas, Dr. St. Cloud Cooper of Fort Smith; from Oklahoma, Dr. M. A. Kelso of Enid; from Kansas, Dr. M. L. Perry of Parsons; Texas, Dr. Joseph Beckton of Greenville; *Secretary-Treasurer,* Dr. F. H. Clark of El Reno, Oklahoma. San Antonio, Tex., was selected as the place for holding the next annual meeting.

The New York State Nurses' Association held its seventh annual meeting in Buffalo on October 20. The following officers were elected: *President,* Mrs. Harvey D. Burrill, Syracuse; *First Vice-President,* Miss Anna L. Alline, Albany; *Second Vice-President,* Miss Ida M. Root, Gloversville; *Treasurer,* Miss Lina Lightbourn, Syracuse; *Secretary,* Miss Grace Arnold Knight, New York City.

The Iowa Association of Health Officers held its annual meeting at Des Moines on October 15 and 16. Dr. M. C. Terry of Brighton was elected president of the Association; Dr. Swazey of Decorah, vice-president, and Dr. Fred Albert, secretary and treasurer.

The Mississippi Valley Medical Association at its annual meeting in Louisville, in October, elected the following officers for the ensuing year: *President,* Dr. J. A. Witherspoon of Nashville; *Vice-Presidents,* Dr. Louis Frank of Louisville and Dr. Albert E. Sterne; *Secretary,* Dr. Henry E. Tuley of Louisville; *Treasurer,* Dr. C. S. Stanton of Chicago. The next annual meeting will be held in St. Louis.

The Lexington County (S. C.) Medical Society held its annual meeting and dinner on October 5, at Lexington. The following officers were elected: *President,* Dr. W. L. Kneece, Baxter; *Vice-President,* Dr. R. E. Mathias, Irmo; *Secretary and Treasurer,* Dr. J. J. Wingard, Lexington. Dr. Wingard has been secretary of the association since its organization four years ago, when the total membership was only five.

The Norfolk and Portsmouth (Va.) Medical Society held its annual meeting on October 13 at Norfolk. The election of officers for the ensuing year resulted as follows: *President,* Dr. W. L. Harris; *Vice-Presidents,* Dr. S. H. Graves, Dr. Joseph Grice of Portsmouth; *Secreary,* Dr. R. L. Payne, Jr.; *Treasurer,* Dr. D. Lee Hirschler. The society decided to hold one meeting each week in the future instead of one meeting a month as has been the custom.

The Eighth District (Texas) Medical Society met in Victoria on October 9, for the annual meeting. The election of officers resulted as follows: Dr. E. A. Malsch of Victoria, *President;* Dr. A. L. Lincecum of Louise, *Vice-President;* Dr. C. W. Letzerich of Sublime, *Secretary and Treasurer.* Wharton was chosen as the next meeting place.

Car Smashes Ambulance.—Ambulance No. 2 of St. Vincent's Hospital while answering a call on October 18 was struck and demolished by a Ninth avenue surface car. The driver was badly bruised but the doctor on the 'bus escaped without injury. The crossing where the accident occurred is a dangerous one, and the cars are supposed to stop before reaching it, but according to witnesses this is not always done.

Obituary Notes.—Dr. Alonzo Brayton Ball of New York died after a short illness in Boston, on October 24, aged 68 years. Dr. Ball was born in this city February 10, 1840, and was graduated from Yale University in 1860, and from the College of Physicians and Surgeons of New York in 1863; he then served for two years on the house staff of the New York Hospital. For some years he was visiting physician to Bellevue Hospital and Professor of Clinical Medicine in the College of Physicians and Surgeons, and at the time of his death was Emeritus Professor. He was also a member of the New York Academy of Medicine, the Association of American Physicians, and the County Medical Society, and consulting physician to St. Luke's and the General Memorial Hospitals.

Dr. Josiah F. Kennedy of Des Moines, Iowa, died at Los Angeles where he had gone for his health, on September 26, aged 74 years. Dr. Kennedy was graduated from the New York University in 1858, and was a member of the American Medical Association, editor of the Iowa Health Bulletin, and an acknowledged authority on hygiene and sanitary science. He was for many years secretary of the State Medical Society and of the Polk County Medical Society, and for twenty-two years was secretary of the Iowa State Board of Health. He was connected with the State University of Iowa for two years as Professor of Obstetrics.

Dr. Carl M. Sears of Paducah, Ky., died on October 1, from burns resulting from the explosion of a gasoline heater, aged 27. He was graduated from the Baltimore Medical College in 1904, and was a member of the Kentucky State Medical Society.

Dr. Turner Anderson of Louisville, Ky., died suddenly on October 9, at St. Mary's and Elizabeth's Infirmary, aged 66 years. Dr. Anderson was graduated from the Cincinnati College of Physicians and Surgeons in 1862, and later studied at the University of Louisville, from which he received the honorary degree of Doctor of Medicine in 1889. He served during the Civil War as Surgeon Major of the Twenty-eighth Kentucky Infantry. He was a member of the American Medical Association, the Kentucky State Medical Association, and the Mississippi Valley Medical Association, and was for some years on the teaching staff of the Kentucky School of Medicine and the Louisville Medical College.

Dr. John E. Parsons of Ayer, Mass., died at his home on October 9, aged 72 years. He was graduated from the Harvard Medical School in 1863, and served during the Civil War as medical officer, and later as assistant surgeon of the Twenty-eighth Massachusetts Volunteer Infantry, and as assistant surgeon in the United States Navy. He was for many years a member of the school committee of Ayer, and a trustee of the public library.

Dr. T. Haven Dearing of Braintree, Mass., for many years a resident of Boston, and one of the oldest practising physicians of the State, died at his home on October 15, aged 83 years. He was a graduate of the Harvard Medical School, and for six years was professor of surgery in the College of Physicians and Surgeons of Boston. He was a veteran of the Civil War, a member of the American Medical Association, the Massachusetts Medical Society, the South Norfolk Medical Society, and the Harvard Alumni Association. He was a member of the State Legislature in 1889.

Dr. George A. Fairlamb died at Bellefonte, Pa., on October 12, at the age of 82 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1848.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PROPOSED STEP TOWARDS COMPULSORY NOTIFICATION—INDIAN SANITARY REPORT—FURTHER NOTES FROM THE OPENING ADDRESS OF THE SESSION.

London, October 9, 1908.

The Local Government Board is about to take a notable step toward compulsory notification of consumption. At present this disease is not included in those which the local authority of a sanitary district can make compulsorily notifiable. But a voluntary system has been adopted in some places with good results, and a few have obtained special acts authorizing them to adopt compulsion. As it is impossible to do this universally without new legislation, the Local Board having power to issue orders respecting Poor Law administration has decided to issue such an order in this case. It will direct the medical officers of the service when the Medical Officer of Health requests them to do so, to send him the names and addresses of all consumptives within forty-eight hours of the disease becoming known to them. Thus the Medical Officer of Health will have all the advantages of the compulsory system so far as Poor Law patients are concerned as soon as he asks for it. This will certainly affect many tuberculous patients—probably many more than might be supposed.

Over one-third of the deaths from tuberculosis in London take place in the Poor Law infirmaries and most of them had been under the care of the parish doctor in their own homes long before they were admitted to the infirmaries. They too are among the most dangerous cases as regards the public health, and it is among them that the disease finds most of its victims. Their unsanitary homes, with their overcrowding, their bad environment, their offensive habits, particularly spitting, are the things that invite the disease. Infected matter is scattered in large quantities, and pending larger powers this attempt to cope with the evil ought to produce some benefit. The local sanitary authorities will be able to help the most helpless. The Medical Officer of Health will ascertain from reliable informants the distribution of the disease in his district and be able to take prompt action to check it. Notices can be served as to obvious defects and the remedies required to meet them. Disinfectants can be supplied to the patient and family. In some cases change of air or admission to a sanatorium may be offered. It may be admitted that voluntary notification has succeeded to some extent, and it is obviously an advantage for those endeavoring to restrict the disease to be informed of its presence in any house.

A report on the sanitary measures taken in India during 1906-7 has been issued and contains details of the sickness and mortality among the military and civil population, also special sections dealing with the medical institutions, vaccination, and other preventive measures. The year 1906 was unhealthy for all classes, the rates of hospital admissions, mortality, and invaliding among European troops being all higher than in 1905. The report further deals at some length with the report of the Plague Commission and also with the preventive measures which are being taken against the spread of other infective diseases.

Following the address of Mr. Rudyard Kipling,

which I reported last week, Dr. A. M. Kellar, B.Sc., delivered the introductory lecture proper at the Middlesex Hospital. He glanced at the development of medicine as a science from early times, touching on the great names from century to century until he came to Lord Lister's theory, founded on the researches of Pasteur. In connection with this he mentioned the introduction of zinc chloride by Campbell de Morgan of the Middlesex Hospital. This was interesting in reference to the ionic treatment, as recent experiments show zinc to be the best coagulating agent. He mentioned a very successful piece of work carried out this year by one of the staff of this hospital, who had discovered how to obviate the terrible effects of a blocking of the axillary lymph ducts by cancer. In reference to preventive medicine he recommended the endowment of professorships, though without much hope, as British statesmen are very parsimonious toward any learning except elementary education. After the lecture many visitors inspected the alterations in two surgical wards prepared for septic cases. It is thought that every improvement has been made and that they are now second to none.

A rather excited controversy has been provoked by the Charity Commissioners respecting the Weir Hospital. The late Mr. Benjamin Weir left £100,000 for a cottage hospital, or other medical charity, for the benefit of the inhabitants of Streatham, where he long resided. The committee and trustees proposed to contribute half the amount to the Bolingbroke Hospital, which is not in the parish. Opposition was naturally raised to this and the Charity Commissioners have proposed a new scheme, which still sanctions the diversion of part of the funds to another parish, contrary to the directions of the testator. An indignation meeting followed when attention was called to the new scheme as one diverting from the parish its rightful funds, and calling on the Borough Council and Committee to take all steps necessary to defeat the scheme, including an appeal to the law courts, and promising the active support of the residents. The Prime Minister, the Home Secretary, and other authorities are also appealed to.

Sir John Broadbent gave the address at St. Mary's Hospital and dwelt on the advances made in recent years, remarking that whereas in surgery the greater the advance the wider the field for the surgeon, in medicine by a curious irony of fate the greater the advance the more limited becomes the scope of the physician. As a result of bacteriological progress and sanitary precautions plague and cholera can get no foothold in this country. Typhus is practically extinct, and typhoid is becoming so. Smallpox would be stamped out but for recent retrograde legislation. Diphtheria has lost its terrors in the presence of serum treatment. Consumption may be under control in the near future. He looked forward to some Utopian era when a host of other diseases which he specified would become rare. Unhappily, the tendency of the British public was to take to the so-called secret remedies advertised in a bare-faced manner in the daily press. These, which cost from three to five farthings per box or bottle, were sold at two to three shillings or more, giving the vendors a profit calculated at two and a half millions of pounds sterling. This is the key to the falsehood so profusely scattered by the press.

Professor Macalister at Kings College took a kindred subject for the address and dwelt on the far-reaching effects of the Darwinian theory. The medical curriculum had been year by year developing by a process of evolution. Anatomy, instead of being the dominant, almost the only subject, had to take its place as one of five sciences in which the practitioner must be proficient. In no other profession was a fundamental knowledge of so many sciences necessary. His advice to the student was to see that the foundations of his technical knowledge were sound, otherwise the superstructure must be weak. No one could hope to master all the sciences, or even to know one as it ought to be known. In the one he had been teaching for forty-eight years he seemed only to be now beginning to sound the depths of his ignorance. Students were sometimes too much spoon-fed by teachers and knowledge so acquired was apt to make only a transient impression on their memory.

At University College Sir Edward Fry made a pleasant speech to the students, in which he reminded them that medicine set before her followers a higher ideal than gain, thus differing widely from commerce. Gain was a legitimate outcome of medical work, but must always be a secondary object—not the primary one. No profession had a more honorable history; it went back at least to the early Greek physicians, and its demands on its followers were not merely great, they were continually increasing. Every true student should say with Solon: "I grow old always learning many things." Moreover, medicine made a demand for moral character. Patience, self-denial, sympathy, and truthfulness were required. As a judge he might perhaps venture to say that he did not find science always in her best robes when she came into court. To hear two experts give precisely opposite opinions was apt to raise a doubt whether science was really existent, or, if so, deficient in truthfulness.

At St. George's Hospital Dr. Slater dilated on the importance of laboratory methods. The knowledge obtained in the laboratory, he said, came to fruition in the wards. Until recently the laboratory had been the handmaiden of the wards, but with the recent developments it seemed to him that the position was becoming reversed. Consultation had ceased to be desirable and had become necessary. It seemed to some as if the immunizator was to be the physician of the future, but he thought there was a want of perspective in such a view. All diseases were not infective, and microbes were not the all-in-all of pathology. The ferment was already above the horizon and threatening the supremacy of the germ. There were regions in which errors in cell metabolism played the principal part. Laboratory work in the last thirty years had rendered practical services which at one time appeared to have only theoretical interest. There were visions of modern therapeutical results far different from the empiricism of the past.

At Guy's Hospital on the 1st inst. Sir R. Douglas Powell delivered an address to the students on "A Just Perspective in Medicine," in which he pointed out that increasing number and complexity of specialties make it necessary that all who practice should cultivate the power of seeing things in their due perspective. He pointed out, too, that there is a temperature proper to each febrile disease, just as the normal temperature is proper to health. In practice they would have to use measures to moderate an excessive temperature because the excess tended to injure the structure of organs—not merely for the sake of lowering the range which might be normal in the disease. He then noticed the work that has been accomplished as to immunity, both natural and acquired, and spoke of it in reference to specific diseases as seen in practice. Some of the cases might be explained by former attacks of which the patients were unconscious and others perhaps by accidental inoculations. Here he mentioned the danger of relapse in phthisis—not so much from a new infection as by the recultivation of localized dormant tubercle through congestion provoked by other septic organisms.

OUR CANADIAN LETTER.

(From Our Special Correspondent.)

MEDICAL COLLEGES IN CANADA—DECREASE IN NUMBER OF STUDENTS—REFORMS URGED IN MEDICAL EDUCATION—SHALL A DEGREE LICENSE TO PRACTISE?—WAR ON ABORTIONISTS—VISIT OF FRENCH SCIENTISTS TO CANADA—AGITATION FOR DOMINION BOARD OF HEALTH—DEATHS IN THE PROFESSION.

The medical colleges at all the university centers in Canada are now open. In nearly every institution there is a marked decrease in the number of students entering the first year. This is generally accounted for by the present financial stringency, although some ascribe the falling off to the criticism excited by the difficulties and length of time—five years—required for completing the medical course in Canada. In the Province of Ontario it is pointed out that there are too many examinations and that it is unfair to demand that the student must pass through not only the ordeal prescribed by the University, but immediately afterwards present himself for the examinations of the Medical Council.

Considerable interest has recently been taken in discussing questions relating to medical education in Canada. Several have expressed the view that the medical degrees of the various universities should confer upon the holder the right to practise his profession in the Province in which he has been educated. In the Province of Ontario all graduates are placed on a level and must pass the examinations of the Ontario Medical Council. Sixty per cent. of the graduates of the University of Toronto failed to pass at the annual examinations of the Medical Council in 1908, and not a few are now advocating that the inde-

pendent examination test should be given up and that the University of Ontario should be allowed to grant the license to practise, as is now done in some other provinces. In the Province of Quebec examiners appointed by the Provincial Medical Council cooperate with examiners appointed by the universities and take joint control of the annual examinations. This provides one test for both the degree and the license, and it is made in the presence of two sets of examiners—one appointed by the University, the other by the Medical Council. It is argued that if the Quebec plan of licensing practitioners was adopted in Ontario complete medical reciprocity between Great Britain and Canada would follow. The medical graduate would not only secure his degree, but in addition be licensed to practise his profession and be registered as a legally qualified practitioner in Great Britain and Ireland. All these privileges are now enjoyed by the medical graduates of McGill and Laval in the Province of Quebec. The advantage is clearly, therefore, in favor of endeavoring to secure for Ontario graduates the same privileges as those enjoyed by the graduates in the sister province. Many favor the change now proposed and are endeavoring to secure united action by the Ontario universities and the Ontario Medical Council to establish the combined examination test, which, it is urged, would be a sufficient guarantee of the competency of candidates. At present the indications point to some medical changes being likely, but in any event nothing will be done to lower the high standard which Canadian universities have set and maintained for medical graduation.

The medical profession in Canada has recently been brought into unpleasant notoriety by the comments of the daily press in alluding to some arrests which have been made in some of the larger cities, of physicians charged with procuring abortion. It was openly stated that some legally qualified practitioners have engaged in this practice and the Medical Council of Ontario was urged to investigate and have the names of all offenders removed from the official register. This attack on the part of the press excited considerable comment, and at a recent meeting of the Medical Council it was by resolution declared: "That the attention of the Ontario Medical Council having recently been called to the prevalence of crime against the unborn, when the Council's detective becomes aware of such a case, he be instructed to lay the matter before the Prosecutions Committee, who will after careful inquiry pass on the evidence, when deemed advisable to the Discipline Committee for action." If a medical practitioner is convicted of a felony his name is at once struck off the register. There is no option in such a case, and whenever a name is removed for such a cause it is never restored. If the offender attempts to practise again he is liable to both fine and imprisonment. The voice of the whole profession in Canada has been aroused lately as never before on this question. The fullest expressions have been made in such a way that there is no mistaking the position taken against abortion. It is urged that every physician should refuse to accept a case (married or single woman) if criminal abortion is asked for. It is also urged in the recent discussions at many medical societies that when a physician is called in to a case of abortion in which the initial stage has been brought on by the patient herself, by one of her lay friends, or by some irregular practitioner, the case should not be accepted without consultation being at once called for. It is held that while a physician may lay down his own life for his neighbor, he should not imperil his own name and injure his family through lack of professional caution in securing further professional advice. The manly, straightforward manner in which the members of the medical profession in Canada have expressed themselves on this subject is most creditable and the Medical Council of Ontario will not hesitate to enforce the most severe penalty on any registered practitioner lending himself to such work.

Montreal and Toronto extended hospitality to the official delegates from France to attend the tuberculosis congress at Washington. The party, numbering twenty-eight, spent several days in Canada. The medical profession of Toronto gave the French scientists a most cordial welcome. After a drive about the city they were the guests of the Dean of the University at luncheon, and afterwards attended a reception at the Academy of Medicine. In this way over two hundred of the medical men of Toronto were given an opportunity of meeting and welcoming the visitors. In the evening the guests were tendered a dinner by the President of the Academy. The visitors expressed delight with the generous hospitality extended to them while in Canada.

As a result of the recent meeting of the Health Congress at Winnipeg there is at present an earnest expression in favor of establishing a National Board of Health for Canada. Hitherto it has been argued that health affairs must be managed and controlled by provincial boards, each province having its own health regulations and administration. It is now urged that the law should be changed so that there shall be a central board to which all the provincial boards shall report. With such important matters as defective and diseased immigrants, the control of tuberculosis, the pollution of streams, and the sanitary inspection of railways, it is urged, there is a wide field for useful work by a national board of health. It is felt by many who recognize the necessity for such an organization that the time is now opportune to advocate this reform.

Several prominent members of the medical profession in Canada have died recently. Dr. George Hodge, Dean of the Western University, London, Ontario, and Professor of Clinical medicine in that institution, will long be remembered for those personal qualities which won for him the esteem of a large circle of friends. His untimely death leaves a vacancy in the Western University, to whose interests he was greatly devoted. Dr. William Hattress was one of the best-known medical officers in the military service of Canada, and while in the discharge of duty at the tercentenary celebration at Quebec a few weeks ago he was taken ill with pleurisy, from which empyema developed. His sudden death came from embolism. Dr. Angus McLennan, who was a member of Parliament, returned from his duties at Ottawa, to his home in Nova Scotia enjoying good health. While addressing a public meeting in his native province he was seized with an illness which in a few days terminated fatally. In Parliament he was ever ready to support measures calculated to benefit public health.

Progress of Medical Science.

Boston Medical and Surgical Journal, October 15, 1908.

Acute Poliomyelitis Following Tonsillitis.—K. Emerson records the case of a boy of eight years, who, after a wetting, developed an ordinary tonsillitis, with rather toxic symptoms for the apparent severity of the lesion. A mixed infection was found in the throat cultures, but no diphtheria bacilli. Under simple remedies he was up and about the next day, but remained cross, irritable, and easily fatigued. Five days after his tonsillitis, he had a tingling in his left hand, felt also in the arm, with headache on the sixth day, left shoulder and posterior cervical region ached on the seventh day, and he became feverish. When seen again by the author the general condition suggested meningitis. On the tenth day paralysis of the deltoid and left upper arm was complete, and two days later he could only weakly flex the left fingers. From this time he gradually improved. The points of interest are the connection of the spinal malady with the antecedent tonsillitis and the very gradual onset of the paralysis. In the usual form of acute poliomyelitis the paralysis usually develops abruptly and is at its maximum intensity during the early days of the febrile disturbance. The author believes that the occurrence of the spinal so soon after the tonsillar attack suggests the possibility of a common etiology.

The Principles Underlying the Treatment of Acute Intestinal Obstruction.—C. L. Scudder's paper is based on a study of 121 cases from the clinic of the Massachusetts General Hospital. The paper is largely statistical and gives a thorough exposition of the subject. The first division of the cases is into nonmechanical and mechanical. The nonmechanical group is subdivided into (1) cases associated with abdominal contusion, (2) with abdominal inflammatory processes, (3) with pneumonia, (4) with acute nephritis, and (5) after clean laparotomy wounds, due primarily to trauma or unrecognizable sepsis. The mechanical group concerns volvulus, and formerly this was foremost in the surgeon's mind, but we now recognize many other factors. In every mechanical case we have an obstruction to the passage of normal bowel contents and also to the circulation in the bowel wall. Symptoms are out of all proportion to the first factor and to the second we must look for the rapidly developing symptoms in some cases. The author goes at some length into the consequences of this obstructed gut-wall circulation. The important and startling clinical fact is the profound intoxication, the toxemia, and the general sepsis. The cause of the toxemia is an acute infection from the damaged wall. These two fundamental conceptions must underlie and be the basis of intelligent treatment. In a suspected case no cathartics should be given by the mouth. Massage should be avoided, food withheld, and no water swallowed. Morphine

conceals symptoms and must be avoided. Early diagnosis permits early operative relief. Special attention is called in cases of intussusception in children to the significance of sudden screams of the child, the characteristic pallor, and the vomiting. We should always carry clearly in our minds the possible types or varieties of intestinal obstruction from the acute pyloric stenosis of early infancy to the chronic obstruction from carcinoma in old age. The two great classes: (1) The nonmechanical; the distended, paralyzed intestine associated with an acute infection; (2) the mechanical; the kinks and twists of coils held snugly against one another; the bands from old inflammatory processes; the intussusception of childhood; the volvulus of adult life. In operating the incision should be in the median line below the umbilicus. The following general rules are given: (1) If the patient is very ill it may be wise to simply, by local anesthesia, open the presenting distended loop and tie in a curved glass tube. This may relieve the immediate distention and allow gases and liquids to pass by what otherwise might become a permanent kink or twist. In such a case no attempt should be made to find the seat of the obstruction at the primary operation. These are desperate cases. (2) Upon opening the abdomen in a case which will permit of more prolonged operation, the collapsed gut should be looked for and followed to the seat of the obstruction. It is difficult to handle distended intestine. The band should be first divided. The bowel above the obstruction must then be emptied of its contents. (3) If the situation is like the following there must be taken into account another factor. A boy, operated upon for acute appendicitis. Drainage is employed. Recovery. Four weeks subsequently acute intestinal obstruction occurs. Operation finds a loop of gut, a foot and a half long, constricted but evidently viable. There are no gross evidences of peritonitis. The bowel is freed, cleansed, and replaced within the abdomen. All is aseptically done. Four days later, because of a persistence of symptoms, the abdomen is reopened, septic peritonitis is found, and subsequently death occurs. The factor to be regarded is the permeability of the intestinal wall. (4) If the gut is evidently dead and there is a thrombosis of the mesenteric vessels, resection of the dead gut must be made. More harm comes from resecting too little intestine in these cases than too much. It does not add to the shock of resection to resect a few inches more. Sound tissue is thus surely reached and the thrombosed mesenteric border is avoided. If the individual is too ill to make an immediate intestinal suture, after emptying the proximal gut thoroughly and flushing it out if wise, the two divided ends should be attached to glass tubes and drawn outside the abdominal incision or well into it, after having caught together the mesenteric borders of the gut. At an early date, four or five days later, when the patient has partly recovered from the initial shock, an anastomosis should be done. In general, operative measures are directed to the relief of the local obstruction; to the diminishing shock by ridding the individual of poisonous intestinal contents, the source of infection; to the early reestablishing of the intestinal canal; to the counteracting of the infection received; to the closure of fecal fistulæ; to the closure of herniæ.

New York Medical Journal, October 17, 1908.

The Cure of Inguinal Hernia Under Local Anesthesia.—A. S. Morrow describes the anatomy of this form of hernia, advocating the use of a freshly prepared 0.2 per cent. of cocaine in hot normal saline for the skin anesthesia and double this strength for deeper infiltration. He gives a detailed description of the operation, specifying just where to make the injections, how to direct the needle, etc. As regards pain caused, he says that the variation in sensitiveness to pain of different patients is so great that it is difficult to make a definite statement in this respect, but adds that in no instance has the patient done more than give facial or verbal expression of the pain. There has been no writhing or squirming about. The advantages of this method are thus specified: (1) No danger from a general anesthetic. (2) Lack of disagreeable after effects for the same reason. (3) Fewer cases of suppuration because in this method gentle handling of the tissues is imperative, hence there is a minimum amount of trauma inflicted. (4) Under local anesthesia the integrity of the nerve supply to the inguinal region is preserved; hence there is less danger of recurrence. (5) For strangulated hernia local anesthesia is especially adapted. These cases are generally toxic and in a precarious condition. A general anesthetic adds the dangers of great shock and of the patient's drowning in fecal vomit. His closing statement is that a local anesthetic is an ideal one for inguinal hernia, and that in a large proportion of cases the operation may be performed absolutely without pain, and at most the pain inflicted during the entire operation will be less than that produced in opening an abscess or an infected finger.

Artificial Hyperemia and Its Therapeutic Application (After Bier).—A. B. Jackson gives a general description of the Bier method, dwelling on its mode of production, devices used therefor, and general therapeutic application. He refers to two personal cases in which it was employed. The first case was that of a young woman with an infected finger in which hyperemia was induced by prolonged wrapping of the finger with a bit of rubber tubing. The case did badly, but improved promptly under the customary wet dressing. The author mentions the case simply as an example of "how not to do it." In the second case, that of a man with an infected thumb, the bandage was applied lightly above the wrist and the patient's pain relieved almost at once. Three hours later the entire hand was slightly hyperemic, but still free from pain. The bandage was removed for about one-half hour; pain began in fifteen minutes. The bandage was again applied, and twelve hours later the patient felt no pain, but still had a marked hyperemia of the hand. For three days the infection was treated by ten-hour stasis and two hours' rest for two periods of the day, and at the end of that time there was no pain or swelling; still neither had incision been made nor wet dressing applied. The author adds that he has treated many cases of acute and chronic arthritis with the stasis bandage, with good results. At first the pain is relieved and motion restored by the solvent effect of the hyperemia. He has had no experience with hot air apparatus, because in neither hospital nor private practice has he had the facilities for applying this method for the production of active hyperemia. Certainly in cases of acute or chronic arthritis, active hyperemia should be employed for its absorptive effect for short periods, after a prolonged application of passive hyperemia by the stasis bandage. In arthritis he has been accustomed to apply stasis bandage for twelve to eighteen hours daily with an intervening period of rest. The bandage is always applied so lightly as to give no inconvenience. In several instances, after the patient is up and moving about, he has shown him how to apply the bandage, and in most cases he has been greatly benefited by his instruction.

Neuromuscular Coordinations Having Educational Value.—L. H. Gulick thus states the four headings under which are classified the major objects for which muscular exercise is taken: (1) Medical education. Under this heading come orthopedic exercises, exercises to develop cardiac power, the reeducation and development of a paralyzed member or of a tabetic, etc. (2) Organic or hygienic education, the general purpose being to increase the general functions of the body, such as circulation, respiration, digestion. This is ordinarily spoken of as "general exercise." (3) General neuromuscular education. This consists of the bringing to complete function those general neuromuscular coordinations that are desirable for the individual to possess. (4) Special neuromuscular education, which may be needed for some specific activity or occupation, such as playing the piano, typewriting, playing billiards, handwriting. In expanding his subject he shows (1) the unitary character of our neuromuscular as well as other acts; (2) their existence in racially old combinations; (3) the hereditary character of these coordinations, or at least a strong tendency toward them, and (4) that on them is built up our mental, moral, social, and ethical life. We should therefore in our physical instruction educate (1) in physiological units and (2) toward racially old and inherited tendencies. The proper curriculum should be along the following lines: In the unguided plays of babyhood no instruction is necessary. Opportunity for free activity, rolling, kicking, and the like is enough. The impulse within the child will lead him to perfect such mechanisms as are then developing. Following these come the games and sports of childhood. Here the child needs help. In old communities, suitable games are passed on from generation to generation of child life without adult aid; but in a country like ours, particularly in our great cities, made up largely of peoples from different countries, different villages, these play traditions are lost. They need to be restored to children by skillful teaching; not by formal instruction, but by that informal leadership which the well-equipped adult can give.

Journal of the American Medical Association, October 17, 1908.

Gas Cysts of Intestine.—J. M. T. Finney reports a case of this rather rare condition in man, and discusses its literature, etiology, pathology, diagnosis, and treatment. The patient was operated on for gastric cancer, a gastroenterostomy being performed, and before closing the abdomen a routine examination of the intestines revealed a curious soft multilocular cystic growth, which was found attached to the ileum about one foot above the ileocecal valve. The numerous cysts were grouped together and varied in size from microscopic to as large as grapes, air escaping with an audible sound on puncture. Some of the cysts were pedunculated; they completely surrounded the intestine, and the whole mass was surrounded by a thin, web-like structure, suggesting an old, partly organized peritoneal exudate. There was no evidence that it encroached on the lumen of the bowel. There were no symptoms that could be referred to this growth. The case is, he thinks, the first reported in this country. The chief interest is in the etiology, which is still obscure, but may yet be elucidated, perhaps from the study of the same or a very similar condition repeatedly observed in pigs, in which it seems to be more common than in man. Gas cysts also sometimes occur in the vagina and bladder of pregnant women, disappearing soon after delivery. The various theories of the etiology are noticed. Finney rejects the idea of a bacterial origin and inclines to the belief that it is a definite type of tumor the cells of which have the power of secreting gas. No evidence of a bacterial origin was found by Drs. McCallum and Simon, or Professor Welch, who examined the secretion. The contained gas closely resembles atmospheric air. The pathology of the condition is also indefinite, though the histologic findings are rather uniform in all cases. The tumor is very vascular and most observers report finding peculiar large giant cells, containing many nuclei. There is no characteristic clinical picture, and the diagnosis is usually made at operation for some other cause or at autopsy. The case reported is the first one associated with cancer. Not much is to be said as to treatment; obstructive symptoms may call for attention, but usually it is overshadowed by other existing affections.

Gonorrhea Vaccine.—W. J. Butler and J. P. Long report opsonic treatment of gonorrhea in female children in 25 cases. The patient's index was taken every other day with very few exceptions and every dose was administered and regulated according to the index. Usually from one to several indices were taken before the inoculations were begun in order to test the immunity wave for the individual during this time. No local treatment was employed. As controls, the phagocytic count of four healthy boys was taken to get an average normal to compare with that of the patients. It is desirable to take at least four cases as a phagocytic count of healthy individuals may vary considerably. On the average the inoculation had to be repeated every fifth or sixth day. Only one strain of vaccine was employed, the authors seeing no advantage in mixed strains. Twelve acute cases, that is patients coming within a few weeks from their infection, were treated. Nine of these patients recovered after an average of 43 days of treatment. The three who did not recover averaged 38 days. There were 13 chronic cases, in 11 of which the patients recovered after a period averaging 39 days. Five cases, one acute and four chronic, were treated with the Rogers and Torrey serum with pretty uniform negative results. The authors conclude that in the treatment of gonorrhea in female children, gonococcus vaccine is more effective than local applications, which they think in some cases actually delay recovery. In many cases, more particularly those of long standing, the vaccine treatment produces marked improvement and often recovery. This does not hold good, however, in all cases, some requiring a very prolonged course of inoculation. The effective dosage varies in different cases and at different times in the same case. It will be best determined by the opsonic index to gonococcus. They found doses varying from 5 to 50 million very satisfactory. In using the inoculations without the index in these quantities inoculation should be given every fifth or sixth day. Doses up to a 100 million only very exceptionally produce any untoward symptoms, but do not seem more effective than smaller ones.

Hydrotherapy in Scarlatina.—D. S. Hanson advocates the use of the tub bath at 90° F. early in the treatment of scarlatina, especially the severe toxic cases, for the nervous symptoms, although in patients with high temperature in whom severe nervous symptoms are lacking the benefits are nearly as marked. He gives the bath for from five to ten minutes, using, at the same time, gentle friction to the body surface. The bath is repeated as often as necessary to control symptoms and temperature. He has used it this way sometimes as often as every two or four hours for three or four days. If a bath tub is at hand the patient may be lowered into it, lying on a sheet, but in his cases an ordinary wash tub was employed. In order that the thermogenic process may not be interfered with seriously, it is necessary that the body be protected after coming out of the bath.

Diagnosis of Functional Paresis.—P. Zenner has been able to confirm the new sign for malingering and functional paralysis described by Hoover (*Journal A. M. A.*, August 29, 1908), and reports his experience with it in two cases. He remarks that it is surprising that, simple and easy as it is, it had not been before described. He calls attention, however, to certain points to be observed in the examination. The complemental opposition, as Hoover calls it—the pressure of the heel of the apparently paralyzed leg into the bed—may not always be very manifest to the hand placed under the tendo Achillis, but will be more evident to observation of the uncovered thigh or to feeling of the thigh muscles. Hoover says in his article that the movements can be carried out in the reverse order; that if a normal person presses one leg against the couch there will be a counterlifting force observed in the other. Zenner tried this test in a number of persons, both normal and paralyzed, but failed in almost every one till he observed the uncovered thigh or felt for the contraction of the thigh muscles, and then he was able to see evidence of this counterlifting action in every instance. It varies, he thinks, to some extent in different persons, but he thinks that the sign may be of special service in some cases.

Perforative Appendicitis in Pregnancy.—E. A. Babler reports a case of perforative appendicitis complicating pregnancy, successfully operated on, and remarks that this is one of the most serious and fortunately also one of the most infrequent complications that may occur in this condition. He is inclined to think, however, that appendicitis occurs with greater frequency than the tabulated cases would indicate, and that as the accident of perforation fails to occur, they are not always recognized. He does not believe, however, that pregnancy predisposes to appendicitis, though it may precipitate an attack in certain chronic cases. Clinically, it does not differ from that occurring in the non-pregnant, and the diagnosis is not usually difficult. As Webster has said, we must bear in mind the possibility of ureteritis and pyelitis. The mortality is due largely to delay, and early efficient surgical treatment is imperative. If perforation has occurred, and if the abscess is localized, incision and free drainage are indicated. It is better to evacuate an appendiceal abscess before emptying the uterus, since it eliminates the possibility of flooding the free peritoneal cavity with pus. If general peritonitis is present, incision and drainage without disturbing gestation are indicated, provided the pregnancy has not gone beyond the fourth or fifth month. In cases near the end of pregnancy, forced labor is indicated.

Antimeningitis Serum.—F. J. Sladen reports the results of the use of Flexner's serum in twenty-one cases of cerebrospinal meningitis in the Johns Hopkins Hospital. From their experience they give their impression substantially as follows: All cases of meningitis in which the meningococcus is suspected should be treated by lumbar puncture and serum injection as soon as possible. The serum does no harm if the case is not meningococcal, and may do good. The course of the disease is changed by the serum—the long-drawn-out cases are not seen, and the terrible sequelæ are rare. The rapidity of the disappearance of the symptoms and signs with the use of the serum suggests an antitoxic property; the positive chemotaxis for polymorphonuclear leucocytes, and the promoted phagocytosis are the most definite and constant features; finally the reduction in number of the diplococci, the change in the staining properties, and the loss of viability, speak for a bactericidal power, although it is a question whether this may not be explained by phagocytosis. Three of their 21 patients died, a mortality of 14 per cent., as compared with 64 per cent. in patients treated without the serum in previous years. One case of the three was a fulminant case, one was complicated with bronchopneumonia of both lungs when received, and the third patient received his first

injection on the fourteenth day of the disease, when he was unconscious, in convulsions, and practically *in extremis*. Sladen and Parker believe that the serum injections should be made daily until there is a drop in temperature and disappearance of symptoms, indicating arrest; and that it should be renewed at any sign of a flare-up.

The Lancet, October 10, 1908.

An Attempt to Rehabilitate the Permanganates.—E. C. Bousfield regrets that the permanganates have fallen into disuse as a disinfectant and claims that they are still one of our most valuable agents in this respect. He supports his claims by certain statistical evidence. He reminds us that the permanganates have many qualities which, given a reasonable disinfectant power, entitle them to consideration. Their very great power as generators of nascent oxygen, their non-poisonous character, their cheapness, and, lastly, their distinctive color, are all features of value, while they alone possess the power of destroying the odor of putrescent matter and of thus affording, in the absence of odor, a very evident, if somewhat rough-and-ready, criterion of the amount of disinfection which has been effected. Finally, they have the advantage of leaving the substance to which they have been applied, whether solid or liquid, in a condition in which it is incapable of giving rise to disease either by the bacteria contained in it or by their products.

The Serum Treatment of Cerebrospinal Fever in the City of Glasgow Fever Hospital, Belvidere, Between May, 1906, and May, 1908.—J. R. Currie and A. S. M. Macgregor present a report largely made up of tabulated material. In the course of the period referred to 330 cases were treated. Of these 105 received automeningococcic serum. In a few cases the specific organism was not recovered, though the symptoms were typical of the disease. With these exceptions all the cases were bacteriologically verified. Four different sera were used, the first in 20 cases with 13 deaths, the second in 6 with 5 deaths, the third in 20 with 14 deaths, and the fourth in 56 with 34 deaths. In other words, 66 out of 102 died. In the remaining three serum cases more than one kind of serum was used, and 2 died. Of the 225 cases not treated with serum 181 died. Details are given as to site of injection, amount of serum used, etc. The authors declare that their convictions are in favor of the serum treatment.

Division of the Auditory Nerve for Painful Tinnitus.—C. A. Ballance reports one case and illustrates it with an excellent picture showing the relations of the various structures located in the field of operation. He says that he is not aware that anyone has previously employed his special technique in dividing the auditory nerve. Details of the operation are thus given: The dura was opened and the cerebellar hemisphere displaced backwards and inwards by marine sponge pressure. On removing the sponges the cerebellum remained in the retracted position, so that the fifth, seventh, eighth, ninth, tenth, eleventh, and twelfth nerves were exposed to view. The eighth nerve was depressed so as to enable me to see clearly the rounded cord of the facial nerve and to avoid injuring it when dividing the auditory nerve. Then the division of the auditory nerve was easily accomplished. No attempt was made to separate the nerve of Wrisberg from the auditory nerve; indeed, the operator did not see it, no doubt because it was concealed by the arachnoid sheath. There was slight hemorrhage from the auditory artery. On recovery from the anesthetic there was conjugate deviation of the eyes to the left, and the eyes could not be moved towards the right. In about forty-eight hours this movement was again possible, but was feeble and was attended by lateral nystagmus with wide excursions. Convalescence was very slow, the pulse remained at 100°, or over, for some weeks, and there was a little difficulty in swallowing due to paresis of the right side of the palate and of the right side of the pharynx. There were occasional syncopal attacks and also paroxysmal feelings of impending suffocation by which the patient was sometimes awakened at night. There was absolute deafness of the right ear. A preexisting palsy was not increased. Two months later there was still slight paresis affecting the right side of the palate and pharynx. Nystagmus was still present. Respirations were 22 and feeble, pulse 100° and regular. Heart was normal, anesthesia and ataxia absent. In two months more the scalp flap was concave and the painful tinnitus had ceased. There was still some weakness on the right side of the face. The tongue deviated very slightly to the left when protruded. There was nystagmus when looking to the right, but less than formerly, and only slight jerks on looking to the left. The palate, pharynx, and vocal cords moved normally, and there was no longer any difficulty in breathing or in swallowing. The sense of taste was lost along the right side of the tongue. There was an area of deficient sensation (as tested with a camel's hair brush) of about the size of a split pea at the junction of the middle of the posterior border of the right external meatus with the concha. There was no affection of any other cranial nerve. The knee- and ankle-jerks were greater on the right than on the left side. The supinator jerks were equal. The pulse was 60. There were no indications of gross disease and no apparent reason why the patient should not get quite well.

British Medical Journal, October 10, 1908.

Tracheal Insufflation in New-born Infants.—This mode of resuscitation was successfully practised by J. A. Swindale in a case of asphyxia neonatorum. A considerable quantity of blood-stained mucus and discharges was extracted by suction through a soft rubber catheter passed into the larynx, and then several portions of clean air were gently breathed into the child's lungs, some being expelled by pressure after each inspiration. After awhile breathing became normal. Several hours after there was a relapse, but a repetition of the maneuver plus a hypodermic of brandy brought the child around again. Further history uneventful.

Bees' Stings and Rheumatism.—This question is discussed by E. W. Ainley Walker, who has conducted a collective investigation among both physicians and laymen, basing his investigations on (1) a possible relationship between some of the phenomena of acute rheumatism and an abnormal production of formic acid in the body under the action of a streptococcal microorganism, and (2) the popular belief that bee sting poison is protective against rheumatism and may also be successfully employed for its cure. Much of the paper is made up of pertinent matter quoted from other writers and cannot be considered here. The author thinks that owing to the prevalence of rheumatism every remedy proposed should be thoroughly tried out, so that one may finally arrive at some definite conclusion with regard to it. He commends a further trial of the method suggested some two years ago by Couch, who has found formic acid a marvelous remedy in rheumatic conditions and in arthritis deformans. He injects formic acid in a 2 1-2 per cent. solution just under the skin in the neighborhood of the painful joints. A preliminary injection of 5 to 8 drops of 1 per cent. cocaine solution is employed, and then an equal amount of the formic acid solution....larger doses cause painful swellings....Several areas may be injected provided that they do not come within two inches of each other. As many as thirty injections have been made, but, as a rule, twelve to fifteen are sufficient for one day. They should be repeated every day, or every alternate day, till the pain ceases.

The Prevention of Sleeping Sickness.—J. L. Todd speaks of the prevailing views as to the nature of this malady and of its occurrence in the Congo Free State. He says that in that locality it is believed (1) that the rapid spread of sleeping sickness could not be explained by the mechanical transmission of the trypanosome by *Glossina palpalis* alone; and it was suggested on various grounds "that other biting insects might also transmit it." (2) As a result of continued observations it was concluded that *Glossina palpalis* was present or might become present in practically every part of the Congo Free State. (3) Sleeping sickness was found to be extremely rife in villages near which *Glossina palpalis* could not be found at the time of our examination. To prevent the disease infected persons must not be allowed to come in contact with the well. All native villages must be removed from the neighborhood of water courses to clear, high ground, free from flies. The areas surrounding native villages should not be occupied by jungle or by tall, shade-giving crops, such as millet, bananas, or manioc; low-lying plants, such as ground-nuts or sweet potatoes, alone should be permitted there. From observations in the Congo it is, unfortunately, certain that such measures as these, although in themselves admirable, would be quite useless in preventing the infection of a population whose occupation normally takes them to localities where the fly exists. It has been noted that communities of paddlers or rubber-collectors are seriously infected, although tsetse flies are never seen within their villages. Again, although as a general rule the clearing of underbrush from about a ford, or a group of buildings, will render the locality comparatively free from flies, it will never completely do so.

Book Reviews.

Ueber den Einfluss der Geschlechtsfunktionen auf die Weibliche Kriminalität. Von Dr. jur. Siegfried Weinberg, Berlin. Halle a S.: Carl Marhold Verlagsbuchhandlung, 1907.

Arndt has said that we are what our sexual organs make us. This exaggerated statement has some basis of truth in abnormal mental states in women, as is well known; and the writer gives us some statistics to show the influence of sexual function in female criminals. An interesting medicolegal borderland study.

A Practical Guide to the Examination of the Ear. By Selden Spencer, A.B., M.D., Instructor in Otology in Washington University. St. Louis: C. V. Mosby Co., 1908.

This is a clinical guide originally prepared for medical students in Washington University, which fact leads one to believe that otology receives much greater attention in that institution than in most medical schools. The plates, five in number, showing the gross anatomy of the ear, are large and definite, while the dozen illustrations are good enough for the purpose intended, although they would not pass muster in a more pretentious volume. Common tests of hearing are briefly described, and there is a chapter on surgical anatomy with reference to the various methods of attacking the mastoid.

A Short Practice of Midwifery. Embodying the treatment adopted in the Rotunda Hospital, Dublin. By Henry Jellett, B.A., M.D. (Dublin University), F.R.C.P.I., Gynecologist and Obstetrical Physician, Dr. Stevens' Hospital; ex-Assistant Master, Rotunda Hospital; Censor and Examiner in Midwifery, Royal College of Physicians, Ireland; formerly Vice-President British Gynæcological Society; late University Examiner in Midwifery and Gynecology, Dublin University; late Externe Examiner in Midwifery and Gynecology, Royal University of Ireland. With a Preface by Sir W. J. Smyly, M.D., F.R.C.P.I., late Master of the Rotunda Hospital. Fifth Edition, Revised. London: J. & A. Churchill; Philadelphia: P. Blakiston's Son & Co., 1908.

This is a handy volume of six hundred pages, and presents the subject of midwifery in a practical way. The opening chapter considers asepsis, the author believing in the routine use of gloves and decrying the use of prophylactic antepartum and postpartum douches. A brief outline of the bony pelvis, the fetal membranes, and the anatomy and physiology of the fetus are then given. The rest of the book considers the practical questions of diagnosis and management of pregnancy, labor and its management, various complications and anomalies of delivery, and postpartum phenomena, diseases, and treatment. Infant feeding and infantile diseases are considered in the later chapters, and an appendix containing the statistics of the Rotunda Hospital for the last seventeen years ends the book. The author is an earnest opponent of "meddlesome midwifery," and recommends the substitution of external for internal manipulations, both in the diagnosis and in the technique of deliveries. He would measure the merits of a practitioner by the infrequency of postpartum hemorrhage, and therefore gives much attention to the third stage of labor. In the practice of infant feeding the author follows Holt, and, indeed, reprints the latter's tables of proper percentages of cow's milk to be used for artificially-fed infants. The book is a very attractive one, and should prove useful to students and to practical obstetricians; the theory of this branch of medicine does not enter into its scope. The reviewer would call attention of the reader to the many titles following the name of the author, which constitute almost a *curriculum vitæ*, and would ask whether a reform is not needed in this matter of enumerating the past and present positions, honorary titles, and appointments conferred upon the authors of medical books.

Diseases of the Nervous System. By H. Campbell Thomson, M.D. (Lond.), F.R.C.P.; Physician to Out-Patients at the Middlesex Hospital, Dean of and Medical Tutor in, the Middlesex Hospital Medical School; Physician to the Bolingbroke Hospital and to the Hospital for Epilepsy and Paralysis, Maida Vale. With 8 Colored and 12 Black-and-White Plates, and 101 Figures in the Text. Chicago: W. T. Keener & Co., 1908.

The author states in his preface that the experience on which his book is founded has been obtained for the most part at Maida Vale and at the Middlesex Hospital clinics, both of which are known to be extensive fields, affording adequate material. The main facts of neurology are clearly and concisely set forth, profuse illustrations acceptably replacing long descriptions or adequately representing conditions briefly stated. Indeed, the illustrations are one of the most attractive features of this small publication. They are all good, not the least useful being the outline figure drawings on which are shown at a glance a summary of the principal symptoms of a disease. This should be very helpful to the student. In the chapter on the reflexes the author states that the Oppenheim response is obtained by stroking the inner side of the leg. Here, we are taught to elicit it by stroking the tibialis anticus. Some of the later methods of treatment, such as nerve grafting, now an established operation, are not mentioned in relation to peripheral palsies, except those of the face and arm. Other recent treatment is not mentioned; *e. g.*, craniectomy in meningeal hemorrhage of the new-born; nerve grafting in anterior poliomyelitis and in infantile cerebral palsy. On the whole, however, the book is a condensed and convenient one, more useful to the student perhaps and general practitioner than to the neurologist.

Diseases of the Spinal Cord. By R. T. Williamson, M.D. (Lond.), F.R.C.P., Assistant Physician, Royal Infirmary, and Lecturer in Medicine, Victoria University, Manchester. With 183 Illustrations and seven Plates. London: Henry Frowde, Oxford University Press; Hodder & Stoughton, 1908.

The author states modestly in the preface that his work is not intended to furnish an exhaustive account of spinal diseases, but to be of service rather as an introductory textbook. His classification, for descriptive purposes, is on a symptomatological basis. Spinal tumors, for example, are described in the section entitled "Diseases Causing Symptoms of a Transverse Lesion of the Cord"; syringomyelia and poliomyelitis, under "Diseases Causing Atrophic Paralysis"; disseminated sclerosis, among "Diseases Giving Rise to Spastic Paralysis," and tabes in the section devoted to "Diseases in Which Ataxia Is a Prominent Symptom." Descriptions are clear and sufficiently comprehensive, and the book is fairly well up-to-date. Each description is followed by a list of references to articles and works which the author has found of most service in preparing the book. The chapter on traumatic affections of the spinal cord is very brief. There is an appendix comprising notes on the more important methods of staining for microscopical study. The illustrations are from the author's own drawings and photographs and microphotographs of cord sections. The book will be found convenient and valuable to the clinician for reference and to the student for systematic study.

The Thirteenth Greatest of Centuries. By James J. Walsh, M.D., Ph.D., LL.D., Acting Dean and Professor of the History of Medicine and of Nervous Diseases, Fordham University School of Medicine; Professor of Physiological Psychology at St. Francis Xavier's and Cathedral Colleges, New York. With Illustrations. New York: Catholic Summer School Press, 1907.

To those who are wont to think that the nineteenth was the greatest of centuries that have been, and that the twentieth is destined to be greater yet, the title of this work will perhaps seem presumptuous, and they will be inclined to regard the book itself, without reading it, as composed in laudation of the "Ages of Faith," in order to please the members of the Catholic Summer School. But even if one approaches the book with this prejudice, a reading of it will convince him that the author is justified in his title, and that in many respects this was one of the greatest, if not actually the greatest, of the centuries that the world has seen. This century saw the foundation of the universities and their development in the establishment of the various schools of science, theology, medicine, and law, and it also saw the establishment of schools of arts and crafts such as the world has never since seen. It was also the age of cathedral building when many of the most magnificent examples of Gothic architecture were erected. Nearly all of the grand English cathedrals were building in that epoch, and they were built by local craftsmen, for each city was too busy with its own work to lend its artists to other cities. In literature the thirteenth century saw the "Chronicles of the Cid," the "Niebelungenlied," "Reynaud the Fox," the "Romance of the Rose," and the "Arthurian Legends"; it was also the age of the Trouvères and the Troubadours, the Meistersingers and the Minnesingers, and Dante was composing the Divinia Commedia at its close. Among the painters were Cimabue and Giotto, among the scholars St. Thomas Aquinas, who taught the conservation of energy and the indestructibility of matter; Duns Scotus, Albertus Magnus, and Roger Bacon. It was in this century that the signing of Magna Charta took place, the first English Parliament met, and the English common law took form, and in the other countries of Europe the foundation of liberty and of the rights of man were laid. Many other things are recorded by Dr. Walsh in this most interesting book to justify his claim that, measured by the work accomplished in every branch of human endeavor and by the uplift of mankind and the promotion of human happiness, the thirteenth century was indeed great, if not the greatest of all.

Society Reports.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Twenty-first Annual Meeting, held at Baltimore, Md., September 22, 23, and 24, 1908.

The President, Dr. E. Gustav Zinke of Cincinnati, Ohio, in the Chair.

Arteriosclerosis of the Uterus.— Dr. Charles M. Rees of Charleston, S. C., pointed out that (1) sclerotic changes in the arterial supply to the uterus were probably of greater frequency than had generally been observed. (2) A pathological change might take place in the uterus independently of general arteriosclerosis. (3) From the frequent physiological changes to which the uterine blood supply was subjected, and the resistance offered, sclerotic changes were favored. (4) That sclerosis and even changes advanced to atheroma with calcareous deposits in the arterial walls of the uterine arteries were found localized in the uterus. (5) These changes occurred in the vast majority of child-bearing women about the menopause. (6) Arteriosclerosis of the uterus might be the cause of alarming hemorrhages, which were uncontrollable by any of the ordinary measures, and hysterectomy was necessary to save life. (7) Hemorrhages caused by arteriosclerosis of the uterus usually came on at the cancer period of a woman's life and could not be differentiated by any other means than hysterectomy and microscopical examination. He emphasized the following facts: (1) That a diagnosis of arteriosclerosis of the uterus was difficult to make, and could only be made where it was possible to exclude every other cause of hemorrhage from the uterus, and by microscopical examination of scrapings from the uterus in which sclerosed capillaries were found, or finally from sections of such a uterus after its removal. (2) Arteriosclerosis, as a definite cause of hemorrhage from the uterus, appearing in women between the ages of 40 and 50, and among those who had borne children, was of greater importance than had generally been determined. (3) That in a fair proportion of cases the hemorrhages from the uterus were in themselves sufficient to endanger the life of a woman and could be made to yield only to hysterectomy. (4) That, with the uncertainty of diagnosis, even after examinations of a section from the cervix and scrapings from the uterus, which showed no evidence of malignancy in women who between the ages of 40 and 50 had borne children, and suffered with frequently recurring hemorrhages, hysterectomy was justified.

Dr. C. C. Frederick of Buffalo, N. Y., said he had seen several cases in the past two years of persistent bleeding in which there was no great enlargement of the uterus, and there was no evidence of any fibroid growth, and likewise no evidence from the scrapings of any degenerative changes in the uterus indicative of cancer. Repeated curettage failed to control the hemorrhage. In these cases he had done vaginal hysterectomy.

Dr. Hugo O. Pantzer of Indianapolis, Ind., said that the frequency of this affection was much greater than was commonly believed, and there was no doubt that many of these patients could be relieved by operation.

Dr. Frederick Blume of Pittsburg, Pa., had operated on three cases of arteriosclerosis of the uterus by the vaginal route by the clamp method in the last two years.

Dr. John A. Lyons of Chicago reported a case of arteriosclerosis of the uterus in which hysterectomy had been recommended by others, but he succeeded in relieving the patient by electricity, using forty milliamperes for from 5 to 10 minutes at a time, the duration of the treatment extending over a month or more, at the end of which time the hemorrhage ceased.

Dr. Charles G. Cumston of Boston said that some years ago he read a paper entitled "Hemorrhagic Metritis," and in it he gave the pathological findings which were chiefly arteriosclerosis of the small vessels of the uterine parenchyma, likewise considerable sclerosis of the uterus. He advised and practiced at the time vaginal hysterectomy, but was vigorously sat on as being too radical.

Dr. Albert Goldspohn of Chicago called attention to the difficulty of making a diagnosis in cases of arteriosclerosis of the uterus; consequently, there was danger of treating some cases under a mistaken diagnosis. Actual cases of arteriosclerosis of the uterus should be treated by hysterectomy, and nothing else.

Hysteria as the Surgeon Sees It.—Dr. A. Morgan Vance of Louisville related a number of interesting clinical instances of hysteria simulating grave organic lesions. He spoke of the methods of cure which he attributed to the power of suggestion and an attitude of command as the controlling elements in vanquishing the obsession of the victims. He suggested the necessity of alertness to avoid error in diagnosis, and attributed his quick and certain success in diagnosis and treatment of some of these cases to that alertness bred of the rivalry in diagnosis which came within his fortunate experience early in his medical career.

Dr. Herman E. Hayd of Buffalo emphasized the difficulty attending a correct diagnosis in cases of hysteria. Everyone had seen patients who had been sadly neglected, and who had been treated for all kinds of hysterical symptoms, when there was really not only one pathological condition at the bottom of them, but various pathological conditions making the case extremely complex; therefore, the reason why so many of these neurasthenic, hysterical, and neurotic women were not cured was not because they had not received good surgery, but because they had not had enough good surgery.

Dr. Charles G. Cumston of Boston had found that the quickest way to make hysterical patients walk, who thought they had hip-joint disease, was to mention in their presence that high amputation was the proper thing, and in a case he recalled, the patient was able to walk in a short time afterward.

Dr. John A. Lyons of Chicago took issue with Dr. Hayd that there was always marked pathology in these hysterical patients, and supported the views advanced by the author of the paper. He believed that in many instances the hysteria could be relieved by suggestion, and cited at length a case that came under his own observation in support of it.

Dr. Roland E. Skeel of Cleveland said that there were two factors in many cases, namely, that while there might be minor pathology, it was only recognized by the patients themselves by reason of over-excitable and over-sensitive nerves, and that physicians really overlooked these two factors. These minor pathological conditions could be found if they were sought for.

Comparative Merits of Abdominal Celiotomy and Colpotomy in the Treatment of Intrapelvic Abscess.— Dr. W. S. Smith of Baltimore read a paper on this subject. He said that if one considered the improvements that had been made in surgical technique, together with the striking results obtained in pus cases by the Fowler postural treatment and the Murphy irrigation, the mortality plea lost much of its significance and force. Recent experience in this connection on the part of the author had been instructive and satisfactory. In the last 110 laparotomies which he had done, there had been no mortality. Of this number, 53 were performed for intrapelvic pus. Drainage was indicated and used in 10 instances, and the Fowler-Murphy treatment was resorted to twice. During the same period of time there had been but 10 colpotomies, and 2 of these were followed by the abdominal operation.

Dr. Charles L. Bonifield of Cincinnati said that vaginal incision was of great importance in selected cases, and the earlier one could get at pus behind the uterus and drain it, the less damage would be done to the uterine append-

ages, and the more hope there would be of curing these patients without a radical operation. Under the most favorable circumstances it was the exception rather than the rule that these patients were cured by this simple procedure. Personally, he had almost completely given up conservative surgery in cases of inflammatory disease of the appendages. Conservative surgery as regards the tubes was more frequently successful than that with regard to the ovaries. In cases in which he had left part of an ovary, the patients usually returned for a subsequent operation.

Dr. Albert Goldspohn of Chicago said that vaginal drainage was permissible in acute pelvic conditions, and the cases amenable to this operation were those in which the focus of pus was located in the pelvic cellular tissue—a parametritis. Intraperitoneal suppurative conditions were not usually benefited very much by vaginal drainage, but more radical measures were needed.

Dr. C. C. Frederick of Buffalo said that in pelvic abscess he preferred the vaginal route for drainage, and then, if necessary, a more radical operation could be done at a later time.

Dr. Frederick Blume of Pittsburg said he had resorted to vaginal incision and drainage in the cases under discussion, and later, if the patient returned, he performed an abdominal operation.

Dr. Joseph A. Hall of Cincinnati said that many pelvic abscesses were the result of tuberculosis, and many of these abscesses were caused by the gonococcus. Vaginal section accomplished much good in some of these cases, but in others more radical operative measures were indicated.

Dr. Louis Frank of Louisville said there could be no question as to the advisability of vaginal incision and drainage in acute pus collections as a temporary expedient. His experience, however, was that in some cases in which it was done abdominal section was required later.

Dr. Joseph H. Branham of Baltimore called attention to the virulence of infection, saying that in some cases the degree of virulence was slight, while in others it was great. As there was a great difference in the degree of virulence of the infection the treatment should vary in different cases.

Dr. Smith, in closing the discussion, said he had not been convinced of the importance of removing a healthy tube, even though the infection was of gonorrheal origin. He thought that a thorough curettement of the uterus and careful exsection of the diseased tube would result in a permanent cure, and there was seldom any necessity for taking out a healthy tube even in gonorrheal cases.

A Simple, Certain, and Universally Applicable Method of Preventing the Serious Accident of Leaving a Sponge in the Abdomen.—Dr. H. S. Crossen of St. Louis, Mo., said that security against this fatal accident was counted one of the unsolved problems of abdominal surgery. The method he had used during the past two years was practically automatic, applicable in emergency work in the country as well as in hospital work. It insured the removal of all gauze without particular attention on the part of anyone. It consisted in the elimination of all detached pads and sponges and the utilization of ten-yard gauze strips, each strip packed in a convenient bag in such a way that it might be drawn out a little at a time, as needed.

Mobility of the Patient After Laparotomy.—Dr. Walter B. Chase of Brooklyn, N. Y., contributed a paper on this subject, in which he stated that (1) the early dictum of the rigid immobility of the patient after laparotomy—yet too much in vogue—was wrong in principle and injurious in practice. (2) Limited mobility of the patient, active or passive, within rational limitations, was admissible and desirable whenever the comfort and advantage of the patient were thereby promoted. (3) The cardinal prerequisites to prompt healing of wounds were perfect coaptation, perfect rest, and freedom from infection. (4) The sitting up of the patient in bed or out of bed the day after the operation, being around the ward the following day, and leaving the hospital for ordinary exercise at the end of a week, was not compatible with sound surgical procedure, even though, in individual instances, satisfactory recovery had followed. (5) By ignoring the pathological conditions present, the burden of proof, that the phlebitis was not due to infection, nor that the mischief attending thrombosis and embolism was not a result of too early mobility of the patient, rested with the advocates of the new departure.

Dr. Albert Goldspohn of Chicago said it was wrong to encourage patients to get up on the second or third day after laparotomy, as it was necessary to wait until cicatrization was fairly complete, and this did not occur in less than about ten days

Dr. Daniel H. Craig of Boston stated that the mobility of a patient after operation had a relationship to the postoperative complications of phlebitis and thrombosis, and he believed that early mobility of patients lessened the liability to these complications.

Extrauterine Pregnancy.—Dr. Herman E. Hayd of Buffalo, N. Y., classified his cases according to their clinical manifestations: (1) The tragic or cataclysmic class, where there was free hemorrhage going on into the peritoneal cavity, with no tendency to localization. Here an immediate abdominal operation was recommended. (2) The cases where a small rupture had taken place and where hematocele more or less circumscribed developed. In this class vaginal incision and drainage was advised, if the pregnancy was not advanced beyond the sixth week, or if the blood clot had not become too firmly organized. (3) Those cases which had gone on to the second and on to the fourth or fifth month, when rupture took place, but the fetal product continued to grow on account of the new attachment it made. (4) Those cases which had gone on to the development of a pelvic abscess with broken-down fetal products in the mass. (5) Those cases which had gone on to term and were delivered by operation when the child was viable, or where the child had died and undergone mummification or calcification as a lithopedion.

Advanced Ectopic Gestation, with Living Child, with Report of Three Cases.—Dr. X. O. Werder of Pittsburg read a paper with this title, in which he said that all these cases began as tubal pregnancy. The time of rupture could be estimated from the history of every case. In none of the cases was the diagnosis attended with great difficulty. Having in the prophylactic instrumental compression of the abdominal aorta a safe and reliable means to prevent the so much dreaded placental hemorrhage, which had really been the principal stumbling-block in the surgical treatment of advanced ectopic gestation, there seemed to be no longer any just ground for other than radical operation in this condition, consisting in the complete extirpation of the gestation sac with living placenta, an operation which in his opinion was the only proper and correct surgical procedure for these cases.

Ectopic Gestation.—Dr. Charles L. Bonifield of Cincinnati divided cases of tubal pregnancy into five classes. (1) Those in which a slight hemorrhage occurred at an early period, six to eight weeks, and killed the ovum. Such an ovum with the blood-clot might be absorbed and the patient regain her health. He reported a case representing this class. (2) Those in which the rupture occurred a little later than eight to ten weeks. In these the hemorrhage was so profuse as to cause well-marked classical symptoms, but was not so profuse as to menace at once the life of the patient. (3) Those which were in immediate danger of death from hemorrhage. This class was not numerous, but it gave rise to practically all the argument as to the relative virtues of immediate and deferred operations. The best course to pursue in the treatment of these cases was to operate at once if the hemorrhage was in progress when the operator saw the

ease, and to defer operation if it had ceased. (4) Cases in which a living fetus had developed to the sixteenth week or later. About fifteen years ago he operated on such a case at the sixth month. The child died in a few minutes, and the mother only survived twenty-four hours. Her death was due to loss of blood caused by the separation of the placenta from the intestines and omentum, to which a large part of it was attached. (5) When the physician has to deal with a dead fetus which has attained an advanced stage of development. The death of the fetus rendered the operation safer for the mother, provided it was not undertaken until a sufficient time had elapsed for a change to take place in the placenta. He had operated on two such cases.

Dr. Albert Goldspohn did not think that all cases of extrauterine pregnancy should be operated on at once. Cases of tubal abortion, in which the ovum slipped out of a somewhat dilated abdominal end of the tube, did not bleed very much, nor did they produce profound shock. On the other hand, it was not safe to assume that in ruptured tubal pregnancy hemorrhage was going to stop, hence it was necessary to operate.

Dr. C. C. Frederick had operated 133 times for ruptured ectopic pregnancy. There were cases of tubal abortion where the amount of hemorrhage was so small and finally ceased, that eventually the women got well without operation.

Dr. Henry Schwarz of St. Louis said there were several cases on record in which women with tubal pregnancy went to term. He had himself operated on such a case. The sac was removed in its entirety, and then opened, disclosing a mature macerated male fetus above the average weight.

Dr. A. B. Miller of Syracuse said that no one could lay down any law which would guide the ordinary practitioner as to the time for operation as he came in contact with these cases.

Dr. Walter B. Chase of Brooklyn said that every case must be a law unto itself as to whether to operate or not.

Dr. Miles F. Porter of Fort Wayne, Ind., said that if a surgeon were called to see a man or woman with a history that she had received a stab wound in the neck and she had symptoms of bleeding to death, naturally he would search for and tie the bleeding vessel. This was the thing to do in a case of ruptured ectopic pregnancy in which hemorrhage was going on.

Dr. Thomas B. Noble of Indianapolis believed in immediate operation in cases of ruptured extrauterine pregnancy, for the reason that if the information went out that these cases were to be treated by procrastination until the diagnosis was certain, these patients would be tinkered with by general practitioners, and the specialist would only be called in to sign a death certificate.

Dr. Frederick Blume emphasized the importance of differentiating what cases should be operated on and which should be left alone.

The subject was further discussed by Dr. Francis Reder and Dr. Roland E. Skeel, and then the discussion was closed by the authors.

Acute Pancreatitis.—Dr. Louis Frank of Louisville said that pancreatic disease until recent years had been very much neglected, and referred to the growing importance of its study. Pancreatic diseases were not all incurable. He referred to the anatomical and etiological factors concerned. He laid stress on the necessity of early recognition. After describing the symptoms he spoke of the treatment as being surgical, and in order to be effective it must be prompt. He reported three cases on which he had operated.

Abscess of Gaertner's Canal.—Dr. Magnus A. Tate of Cincinnati spoke of the rarity of this condition, and reviewed the literature of the subject. He reported the case of a woman 36 years of age, who for some years had had a number of very peculiar attacks. The trouble began with a pain in the pelvic region accompanied by rigors, this being followed by distinct chills, rapid pulse, and high temperature. This would last from a few days to a week or two, then there would be a vaginal discharge of a little pus, which was always followed by a subsidence of symptoms, and an apparent recovery would ensue. There was some tenderness elicited over both the right and left lower sides of the pelvis. After complete anesthesia a vaginal examination disclosed a small anteverted uterus, but no tubes or ovaries could be palpated. On the right wall at a central point between the anterior and posterior vaginal walls was found a decided thickening, and on tracing it up, it felt like a ridge of massed tissue which passed up to the side of the cervix in the vaginal vault. He opened the posterior cul-de-sac, and after packing some gauze in the back of the uterus he opened up this ridge of vaginal ligament as far as he could. The following day the gauze which had been placed in ridge tissue was bathed in pus which was constantly being discharged. The temperature subsided and patient recovered.

Cesarean Section.—Dr. C. C. Frederick of Buffalo gave a résumé of the present status of this operation, and said that until within recent years it was appealed to only as a last resort in obstetrical delivery The consensus of opinion was now becoming favorable to cesarean section as being preferable in contracted or deformed pelves to protracted high forceps operation, version, symphyseotomy, or pubiotomy.

The Development of the Human Ovum During the First Eight Weeks of Pregnancy.—Dr. Henry Schwarz of St Louis called attention to the fact that all textbooks of obstetrics described the ovum and fetus at the end of ten periods of twenty-eight days each, and they all, without exception, declared the ovum to be of the size of a pigeon's egg, and the fetus of a length of 7 to 10 millimeters at the end of the first lunar month, that is to say, before the woman's menstruation was overdue. The fact was, the youngest ovum on record, that of Peter, which was the size of a hemp seed, was found when menstruation was three days overdue, and belonged therefore to the middle of the fifth week of pregnancy, or to the beginning of the second lunar month. At the end of the first lunar month the ovum was still a very small body, and passed through the uterine end of the tube just about the time when menstruation became overdue. All ova varying in size from a millet seed to a hen's egg belonged to the second lunar month, and their description had to be rearranged. He believed that ovulation, as a rule, preceded menstruation, and that the impregnated ovum dated from the first menstrual period which had been suppressed; that during the first lunar month of our present counting pregnancy existed only during the last few days, and that during these days the ovum migrated through the tubes without noticeable increase in size, reaching the uterine cavity about the day of the expected menstruation, and there casting off its shell of zona pellucida, as demonstrated by Spee for the ovum of the guinea-pig.

President's Address: Solving the Problem of Obstetrics.—The president, Dr. E. Gustav Zinke of Cincinnati, reviewed at length some of the important events in medicine and surgery of the last one hundred years. He compared the old and new methods of managing the pregnant, parturient, and puerperal states. Reference was made to the changes in the practice of midwifery within the last fifty years. There was practically no improvement in the maternal and fetal mortality and morbidity of midwifery during the last twenty years. The present rate of obstetric mortality followed immediately that of tuberculosis. Eclampsia, placenta prævia, oblique and transverse presentations, narrow and contracted pelves, were conditions which precipitated in every instance a conflict unto death between mother and child. The problem of preventing this conflict was gradually being solved by the aid of anesthesia, antisepsis, asepsis, the forceps, sym-

physeotomy, pubiotomy, hebotomy, and cesarean section. The gradual elimination of the induction of premature labor, prophylactic version, the high forceps, and perforation of the living child had begun. The problem of obstetrics would be solved when the custom of sending the pregnant and parturient women—victims of complications—to a maternity had become an established practice.

Intraligamentous Fibroids.—Dr. JOHN F. ERDMANN of New York said that during the past seven years he had operated upon 61 cases of fibroids, doing 48 hysterectomies and 13 myomectomies. Of this entire number he met with 5 cases of intraligamentous fibroids, one of which was a case of multiple fibroids of the uterus, with two discrete ones in the right broad ligament. The remaining four were true intraligamentous fibroids in the full sense of the word. None of these intraligamentous masses in any of the five cases had any association with the uterus, except one, in which the association was due to an inflammation occurring in the pelvis, and an exudative or plastic adhesion to the uterus was evident. In 4 of these cases the tumors were hard or of the same consistency as ordinary fibroids. In the large round one the feeling was of a decidedly soft nature. The author reported the five cases in detail, with recovery in all of them.

Uterine Fibroids Complicating Pregnancy.—Dr. WILLIAM J. GILLETTE of Toledo, Ohio, read a paper on this subject in which he reported cases. The points he desired to bring out were, that in the presence of a pregnancy, should (1) operations for the removal of fibroids be limited to the fifth month, and if not, and limited to any time, what should that time be? (2) That not only pedunculated and subperitoneal tumors might be removed, but interstitial as well, without the interruption of pregnancy (3) That even very small fibroids may be so situated as to become of lethal significance. (4) That fibroids tumors might practically disappear at this time or shortly subsequent to it. (5) The possibility of the removal of pedunculated fibroids during labor, allowing it to progress naturally.

Myoma of the Cervix Uteri.—Dr. FRANCIS REDER of St. Louis made some remarks on this subject, reported cases, and exhibited specimens.

Ovarian Cystoma Complicating Pregnancy.—Dr. CHARLES G. CUMSTON of Boston, Mass., said that the indication for operative interference during pregnancy was usually the severity of the symptoms. The cyst should be removed by abdominal incision or posterior colpotomy, according to the situation and size of the neoplasm. Cooling of the abdominal cavity was to be avoided during operation, as it was an important factor in the production of premature labor. The favorable results obtained when operation was done during the first few months of pregnancy were not accidental, and a timely removal of the cyst might prevent threatened miscarriage. Operation should be advised as soon as a diagnosis of cyst had been made, in order to avoid complications due to the presence of the tumor during pregnancy, labor, or the post-partum period.

Subdiaphragmatic Abscess.—Dr. JOHN W. KEEFE of Providence, R. I., defined an abscess of this character as a collection of pus, or pus and gas, which lay in contact with some portion of the under surface of the diaphragm. It was rarely the result of a traumatism, but was generally due to some previously diseased condition. The author reported six cases, and the main facts which he emphasized were the avoidance of the transpleural route; the dangers attending the use of the aspirator needle and the unnecessary resection of the ribs; the advocacy of exploratory abdominal incision, with drainage through the same or in the tenth or eleventh interspace, in the post-axillary line.

Injuries to the Bladder Taking Place During Hernia Operations.—Dr. ROLAND E. SKEEL of Cleveland, O., said that since the appearance of Bruener's article in 1898 and Moynihan's in 1901, bladder herniæ were apparently increasing in frequency as shown by 144 cases collected since 1896, as compared with the 181 in the literature previous to that date. These herniæ were no more frequent than before, but present methods of operating as well as increased care in looking for them accounted for the more frequent report of such cases. The cases reported showed a large proportion not diagnosed until operation, and unfortunately a great number were not recognized until the bladder was injured and a fair per cent. were not recognized even at the time of injury. Many of these cases were artificially produced by traction upon the sac and efforts to place the ligature high up resulted in catching the bladder wall in its bite. In addition to the ordinary method of recognizing the bladder by the appearance of the prevesical fat and the large veins on the fundus, the administration of methylen blue for a day or two previous to hernia operations would cause instant recognition of the bladder injury if it occurred Such a routine measure was justified by the fact that the mortality rate for hernia operations was practically *nil* aside from accident.

Surgery of the Spleen, with Special Reference to Trauma; A Method of Encapsulation.—Dr. WALTER C. G. KIRCHNER of St. Louis reported twenty-two cases of injury to the spleen treated by splenectomy and other methods. After describing the various symptoms of injury to the spleen, the writer described a method of treating hemorrhage from the spleen by encapsulation. In this operation the spleen was brought forward and delivered into the wound as in splenectomy. Wide sutures were inserted through the spleen to approximate the fractured or cut edges, and these sutures were also used to retain the omentum which was wrapped over the spleen to form a sort of capsule The organ was then replaced in the splenic fossa, and held in position by means of packs.

Treatment of Typhoid Fever Perforation.—Dr. JOHN D. S. DAVIS of Birmingham, Ala., had operated in ten cases of typhoid fever. In nine perforations were found. Of this number there were eight recoveries and two deaths. One typhoid case was operated on, with recovery, in which no perforation was found. Two were perforations of the ileum; one had a perforation in the ileum and at the base of the appendix; one had two perforations of the colon, ascending and transverse; four were appendicular, one of which later had a perforating anastomosis between the ascending and transverse colon. In the last fatal case there were two perforations in the ileum. All the cases were drained except the one in which no perforation was found. Incision in the outer border of the right rectus fascia was made in each case. In one case the pus was mopped out and drainage effected through a stab wound. He recommended the Murphy method in treating many of this class of cases, with accumulations of pus, large or small, particularly where there was not much fecal extravasation.

Some Old Fallacies in Retroversion Surgery Revived.—Dr. ALBERT GOLDSPOHN of Chicago, in a paper on this subject, said it was an anatomical fact that the round ligaments of the uterus, irrespective of what might be their normal function ordinarily, were the only available means or medium for a harmless and permanent cure of retroversion in fruitful women, because they alone among the various uterine attachments were a part of the uterus itself and as such underwent evolution and involution with that organ during and after gestation. Years of abundant clinical experience had set forth the great value practically of this anatomical fact. This experience had been dearly paid for by numerous shameful parturient deaths from dystocia following vicious surgery for a minor ailment that, in itself, would never cause death. Nevertheless, two articles had recently appeared that rather ignored the above-mentioned experience, and advocated principles and procedures which gynecologists had threshed out and discarded as old straw some time ago.

Typhlitis.—Dr. John A. Lyons of Chicago said that all cases of typhlitis and perityphlitis need not necessarily be secondary to appendicitis. He reported a case of abscess of the cecum in support of this claim. The patient had suffered for several months from what were supposed to be recurrent attacks of appendicitis, and during the last one the speaker found the patient had suffered (1) from sudden severe abdominal pain; (2) nausea and vomiting; (3) general abdominal sensitiveness over the appendix, and (4) elevation of temperature to 102° F., soon after the onset of the severe pain. These were Murphy's cardinal symptoms for appendicitis, and making a diagnosis of appendical abscess because of a large fluctuating mass involving the entire iliopsoas region, he ordered the patient to the hospital, and after a hurried preparation made an incision over the tumor, when, to his surprise, he found a large abscess of the cecum. The appendix was in its usual position and apparently normal in every respect, excepting where it was about to be involved at its extreme distal end in the perityphlitic inflammation. After cleaning out the abscess cavity, cutting away all gangrenous, loose, and raw edges, he removed the appendix, which, upon examination, proved to be normal, except as above noted. A peculiar feature followed the operation, in that the patient, who had suffered from childhood with enuresis, wetting the clothes both night and day, had been entirely relieved of this annoying condition, it not having recurred, whereas it was frequent in occurrence before the operation. The author accounted for the cure of the enuresis by saying that ganglionic sympathetic fibers joined to the fourth sacral nerve, which latter supplied the neck of the bladder, must have been released from abnormal pressure by the complete cure of the inflammatory product.

Repair Rather Than Removal of the Generative Organs of Women.—Dr. John E. Cannaday of Charleston, W. Va., discussed the advisability of trusting pelvic inflammation, especially that of the gonorrheal type, to nature, and treating the results of infection by operation, if need be, later. He spoke of the need for treating certain cases of infection in accordance with the social condition of the woman. The time requirements of palliative treatment were being extended. He pointed out the advantages of not operating until physiological resistance to infection had been well established. Much of the so-called palliative treatment was useful only as a means of diverting the mind of the patient. Subinvoluted prolapsed organs after suspension and perineorrhaphy would, as a rule, be speedily restored to normal size by the relief of congestion incident to malposition. Local infections might be best attacked by local applications. Repair rather than removal was to be commended in general.

Experiments Upon Animals Relative to the Question of Abdominal Supporters After Laparotomy.—Dr. Robert T. Morris of New York described a series of experiments which he had conducted upon animals which showed that it was unnecessary to subject patients to the annoyance of abdominal supporters so frequently as was commonly proposed. The author did not employ them in one per cent. of his laparatomies.

The following papers were also read: "Factors of Safety in Abdominal Operations, Based on Operations," by Dr. Geo. W. Crile of Cleveland, O.; "Report of a Case of Gastric Tetany; Operation; Recovery," by Drs. John Young Brown and William Engelbach of St. Louis, Mo.

Officers.—The following officers were elected for the ensuing year: *President,* Dr. William H. Humiston of Cleveland, O.; *First Vice-President,* Dr. James Edgar Sadlier of Poughkeepsie, N. Y.; *Second Vice-President,* Dr. William A. B. Sellman of Baltimore, Md.; *Secretary,* Dr. William Warren Potter of Buffalo, N. Y.; re-elected; *Treasurer,* Dr. X. O. Werder of Pittsburg, Pa., re-elected.

Fort Wayne, Ind., was selected as the place for holding the next annual meeting; time, third Tuesday in September, 1909.

AMERICAN ORTHOPEDIC ASSOCIATION.

Annual Meeting Held in Chicago, June 4 to 6, 1908.

Henry Ling Taylor, M.D., of New York, President.

Thursday, June 4—First Day.

Present-day Needs of an Orthopedic Service.—Dr. Henry Ling Taylor of New York delivered the presidential address, entering this as his title.

Treatment of Joint Tuberculosis by Marmorek's Serum.—Dr. Albert H. Freiberg of Cincinnati read this paper, reporting the progress of cases described at last year's meeting, and giving some new cases treated since.

The Treatment of Some Types of Rheumatoid Arthritis.—Dr. Frank E. Peckham of Providence presented an account of the results of the treatment of villous, atrophic and infectious arthritis by means of electric and other baths, vibration, and gymnastics.

A New Treatment for Old Tuberculous Sinuses.—Dr. John Ridlon and Dr. Wallace Blanchard of Chicago were the joint authors of this paper, which was read by the latter. The treatment consisted in injections of bismuth and vaseline emulsion.

Dr. Emil Beck spoke of some of the limitations of the method, so as to put orthopedists on their guard against them. He thought, however, that its use was not attended with much danger, there having been no bad accidents from it. It should not displace other methods.

Dr. H. Augustus Wilson thought that a fluid which melted at a low point was better for small sinuses.

Dr. Gwilym G. Davis of Philadelphia asked whether any bad effects were likely to arise from the use of paraffin and vaseline, these being mineral in character and apparently almost unabsorbable. He had not used bismuth, but had used a mass of iodoform, wax, and oil of sesame or olive oil.

Dr. Freiberg had used for several years a thin suspension of bismuth for the purpose of diagnosticating the extent of these fistulous tracts. He thought, however, that as long as destruction at the seat of disease was going on, it would be useless to close the fistula.

Dr. Philip Hoffman of St. Louis wondered whether some of the many sinusus shown in radiograms of such cases might not be dissection-sinuses produced by the force used in injecting the bismuth.

Dr. Rugh stated that, in the postmortem examination of a part of the face that had been injected subcutaneously with paraffin for the correction of a deformity, it had been found that nature was appropriating the material by throwing out new tissue through the injected mass, thus making it actually a part of the body.

Dr. Blanchard said that the bismuth was not intended as a treatment for the tuberculosis, for which the patients were being treated at the same time by other means. He had found no bad mechanical effect from the injections. The method was not used in cases of acute inflammatory conditions, but only for old chronic sinuses. He saw no reason for changing the formulas employed.

The Influence of Weight Bearing on the Treatment of Tuberculous Joint Disease.—Dr. Virgil P. Gibney of New York presented this paper.

Deformities in Feeble-minded Children.—Dr. E. H. Arnold read a paper on this subject. Conspicuous findings were the following: the preponderance of females, the high percentage of Hebrews, the comparative sterility of the parents, the large number of families having more than one defective child, the fact that instrumental delivery was a possible cause in some cases, the large proportion of mouth-breathers, the tardy beginning of walking and talking, the prevalence of left-handedness, the fact that very few feeble-minded children escaped deformity, and the conclusion that most of these deformities were acquired and due to habit. He then considered the prophylaxis in some of these conditions, and the value

of educational measures in forming good habits and overcoming bad ones.

Dr. Bert E. McKenzie of Toronto believed that instead of one of these conditions being dependent upon the other, both were due to a common cause—a brain-lesion at some time, and frequently before birth. In correcting these deformities, he depended greatly upon education, upon which he laid great stress. If he could not have the co-operation of the patient, as is impossible in the feeble-minded, he hesitated to enter upon the more distinctly surgical aspect of the correction of deformities.

Dr. Young said he would like to have the attention of the profession called to the fact that forceps was often used unnecessarily, and its use often resulted in the deformity of the child.

Mr. Ernest Muirhead Little of London said that in a certain proportion of spastic cases the pressure of the forceps probably caused the lesions with which the surgeon had to deal.

Tuberculin in Orthopedic Surgery.—Drs. John Joseph Nutt and T. W. Hastings read this paper. The report was based on twenty-two cases of joint tuberculosis, and the details of the administration of the tuberculin were fully described.

Mechanical Lesions of the Sacroiliac Joints.—Dr. Ralph R. Fitch reported twenty-two cases, divided in groups according to etiology. Treatment began with support, and he described a method of applying plaster of Paris jackets with the back in a hyperextended position, without special apparatus.

The Nonoperative Treatment of Fracture of the Femoral Neck.—Dr. A. M. Forbes referred to the grave prognosis in medial and intracapsular fractures, and the decreasing tendency to osseous union as the fracture approached the smaller portion of the neck near the head. A consideration of the anatomy of the fracture and the anatomical principles of treatment and a critical review of the methods of treatment that had been advocated led him to conclude that under certain forms of treatment there was probably a more hopeful prognosis than most surgical writers indicated.

Dr. Hoffman gave the details of several cases in quite old ladies treated by the Whitman method some time after the occurrence of the accident with good results. He thought that if good union could be secured under such adverse conditions, to get it must be merely a matter of technique. He remarked that a person inexperienced in the application of the plaster of Paris could make the patient very uncomfortable. Pads should be used, and then the patients were more comfortable than with the old traction method. They could be shifted around in bed, and bed-sores did not occur.

Dr. Aaron J. Steele of St. Louis considered fracture of the thigh-bone to be due to old age, at which period changes had taken place that caused the thigh to be broken very easily. He referred to what might be called a figmental ligament, a thickening of the capsular ligament running along the under side of the neck, and said that when the thigh bone was fractured from a slight cause in elderly people, the figmental ligament might act as a splint and hold the parts of the bone together. If in such cases the patient were confined to bed and slight traction made, the union would probably take place without much trouble.

The Cause of Atrophy in Joint Disease.—Dr. Arthur T. Legg read a paper giving the results of a comparative study of the atrophy of disuse alone and that caused by joint irritation. The results of animal experiments led him to conclude that, since the atrophy of disuse was brought about in a complex way by the vasomotor system controlling the nutritive equilibrium of the body, the atrophy seen in joint disease was brought about in the same way; namely, through functional inactivity.

The Anatomy of Congenital Dislocation of the Hip.—Dr. W. G. Turner discussed some of the anatomical causes predisposing to the occurrence of dislocation, and the importance of proper fixation adapted to anatomical conditions. He demonstrated the class of cases in which the axillary abduction position is indicated, and showed diagrams of seven cases illustrating the varieties of skeletal variations previously discussed.

Friday, June 5—Second Day.

Actinomycosis of the Ribs and Vertebræ.—Dr. James K. Young said that in this case there was no history of exposure to the contagion. The disease began with difficulty of deglutition. A large scapular abscess was followed by infection of the ribs and dorsal vertebræ. An operation was performed, a description of which was given by the author; but the disease continued to extend, and had a fatal termination.

Myositis Ossificans.—Dr. Charles F. Painter described two principal types of this disease, the progressive and the traumatic, and reported two cases, considering the etiology, the gross and microscopical pathology, the clinical course, the operative and medicinal methods of treatment, and the prognosis.

Blastomycosis Resembling Bone Tuberculosis.—Dr. Edwin W. Ryerson of Chicago, said that the first patient, a young man, apparently suffering from an old knee-tuberculosis, had an acute localized suppuration in the outer malleolus, followed by similar affections in many other joints. The second case was that of a young man with apparent dorsal Pott's disease and pulmonary tuberculosis, who developed typical blastomycosis. Both cases were fatal, and an autopsy was obtained in each.

Bone Fragility and Eburnation of Rickets.—Dr. Wallace Blanchard said that rachitic bone might be so friable that the long bones of the legs would break under the body weight, or with a change of diet and environment might eburnate in two months to nearly the solidity of adult bone. He presented cases showing a quick change of bone structure from extreme friability to comparative solidity and strength.

Dr. Fred H. Albee opened the discussion on this symposium by adding two more cases of myositis ossificans to those reported by Dr. Painter, exhibiting *x*-ray pictures. In the second case there was no history of injury, and no pain; just a flexion deformity at the knee-joint.

Dr. Riely described a case that he had seen and believed to be myositis ossificans. There were flat, hard plates at various portions of the body, some of which were permanent and some transient. The patient had had rheumatism and had rheumatic endocarditis.

Dr. Little referred to one of Dr. Blanchard's cases, in which, after an operation for bowlegs, a knockknee had appeared, resembling a case of retrogressive rickets. He believed such cases to be more common than was generally supposed. Some surgeons believed them to be cases of osteomalacia, and not rickets; but the postmortem microscopical appearances in one of his cases had been those of rickets. He asked for the experience of the members in regard to the prevalence of late rickets, and also desired to know whether they thought it of any use to do an osteotomy in such cases.

Dr. Painter said that he had had an undoubted case of osteomalacia some years ago, and had lately had one of adolescent or recrudescent rickets. Both had developed at about the age of puberty, and in both the attempt to take out the bend proved fruitless. He thought that recrudescent rickets was a form of osteomalacia.

Dr. H. L. Taylor mentioned a peculiar case seen by him and Dr. Albee within a few weeks, in which the diagnosis of myositis ossificans was made, but in which the *x*-ray disclosed a needle.

Dr. Davis thought that the condition known as Madelung's disease might be a condition of late rickets. In this disease subluxation occurred at some points, progressing

to a moderate degree, and then remaining stationary. He had had such a case in which good union was secured after osteotomy.

Dr. Blanchard, in closing, said that he had believed it to be thoroughly understood that adolescent rickets was different in nature and pathology in every respect from infantile rickets.

Some Notes on Fibrous Ankylosis of the Knee.—Mr. E. Muirhead Little of London said that in the majority of cases of stiff knee the ankylosis was fibrous. He then considered the cause and the symptoms of the condition. The treatment differed in its objects in the upper and lower limbs. In the former, free mobility was the greatest desideratum, while in the latter, a firm support to the weight of the body was the thing wanted. The worst cases of fibrous ankylosis must be treated the same as bony ankylosis. Excision of the joint should not be done before the age of fourteen; and even then, the epiphyseal lines should be respected. Mr. Little had not found pins, nails, screws, or wires necessary in the case of the knee. He quoted some illustrative cases.

When Is Bony Union Complete After Excision of the Knee?—Dr. J. T. Rugh of Philadelphia after a review of the literature of the subject and an exhaustive consideration of all the facts, formulated the following conclusions: (1) Writers and operators differed as to the length of time fixation or retention apparatus should be worn after excision. (2) Flexion deformity was much more likely to occur before twelve years of age, when union was fibrous or cartilaginous. (3) Bony union was more probable after this period, by reason of the increased activity on the part of the osteogenic tissues. (4) Deposit of bone normally took place more slowly in the epiphysis, because of the histological structure of the parts. (5) Intrinsic influences might and did retard the process of healing after excision. (6) Extrinsic factors also delayed the ultimate bony union. (7) Bony union after fracture of the shaft of a long bone was not complete for from nine months to a year, and it would require nearly as much more time for completion in the epiphysis. (8) During operation sufficient periosteum should be preserved to cover entirely the line of contact of the excised parts, and accurate coaptation and as nearly absolute fixation of the bone-ends as possible should be secured. (9) Fixation should be maintained for a period of at least one year, and probably nearly two years, after excision, to avoid the danger of flexion or other deformity.

Dr. Walter G. Stern of Cleveland asked what had been the experience of the readers of these two papers in resection for flail kneejoint after infantile paralysis and for a bad position after rheumatoid arthritis. He had had humiliating experiences in both classes of cases.

Dr. Young said that when his attention had been first attracted to the operation of osteotomy above the knee for ankylosis with deformity, he had not thought a great deal of it; but that after having performed it on children from twelve to fourteen years of age with satisfactory results, he had become much in favor of the Ollier operation. He believed that in future the opening of the kneejoint would be a frequent procedure.

Dr. Robert Osgood said that he had excised the knee in a case of what was supposed to be rheumatoid arthritis, and in which the microscopical examination had seemed to make this diagnosis certain. The patient had now a stiff, solid knee.

Dr. Little said that when the case was fairly put to them, the patients did not like the idea of an operation that would cause them to have a stiff knee. He had found that in infantile paralysis the bones united well, although he had had one very bad experience after having done an arthrodesis of the ankle, and a subsequent arthrodesis of the knee. The extra strain on the popliteal muscles had produced a gangrene of the front of the foot. He did not consider Ollier's an ideal operation, because, instead of correcting a deformity, one was adding another deformity to that already existing.

Dr. Rugh said that he had done excision of the knee for a case of infantile paralysis in a woman of forty-eight years. He had had no experience with excision after arthritis deformans. He believed in promising the patient bony union after a period of about two years, although fibrous union might occur in from four to six weeks.

Preliminary Report of a New Operation for Arthritis Deformans of the Hip.—Dr. Fred H. Albee described this operation, and said that firm ankylosis was produced with the leg in a corrected position. He reported five successful cases. All the patients had been incapacitated for some months or years. One did not require any elevation, while others were wearing up to half an inch on the heel of the affected leg. In every case the pain had been entirely relieved.

Dr. Arnold said that he had seen one of the cases previously and operated upon it. In the *x*-ray picture taken at the time, he could not distinguish any osteophytes. The operation was at first quite successful; but later, walking up stairs had begun to make the patient tip forward.

Dr. Young said that after excision the joint was not so stable as after Albee's operation, although the motion is good.

Dr. Turner thought it would be of extreme value to the Association if Dr. Albee would report upon the condition of these patients at the next annual meeting.

Dr. Painter said that the Murphy operation did not give enough motion to be of much value, excision was fruitless, and osteotomy was unsatisfactory when much deformity was present.

The Question of Balance and a New Form of Shoemaker's Last.—Dr. Ansel G. Cook of Hartford read these communications. The first was an elementary study of the balance of the human body and its relation to the balance of shoes, including rules for designing or for judging of the efficiency of shoes. The second was a further extension of the usefulness of plaster of Paris, enabling the orthopedic surgeon in a measure to escape from the thraldom of his shoemaker.

Dr. Ridlon said that instead of using a board to step the foot on when making the cast, he used a piece of sheet steel, bent according to the height of the heel needed for each particular foot.

Dr. Riely said that he used aluminum for the same purpose. He had found that the use of a bandage around the plate and the foot had tended to flatten the arch and spread the heel.

The Operative Treatment of Bony Ankylosis of the Knee, Hip, and Elbow Joints.—Dr. J. B. Murphy of Chicago described an operation by which he prevented bony union after operating on the knee joint, by the interposition of a flap of muscular tissue, with fat and fascia between the divided ends of the bone. This resulted in the production of a sliding joint with a pseudo synovial membrane. The lateral ligaments were completely excised. The treatment was also applicable to the elbow and hip. He also described a process of injection by which he rendered joints immune to infection. The solution injected consisted of formalin and glycerin. In every case prepared in this way there was an entire absence of inflammatory reaction.

Dr. Young asked why Dr. Murphy removed the lateral ligaments entirely. He thought that if they could be saved it would be an advance in the treatment of the condition.

Dr. De Forrest Willard of Philadelphia also thought that when both these ligaments were removed the joint would not be strong enough to support the body satisfactorily.

Dr. Ridlon asked whether Dr. Murphy's results were usually good in cases of gonorrheal inflammation of the joint.

Dr. Davis said that the crucial test of the operation was in the knee joint, and he desired to see a perfectly good result in this joint. He had operated on a case according to Dr. Murphy's procedure, but, instead of transverse division of the patella, had used lateral incisions, turning in lateral flaps. He got too much motion; so he excised less in the next case, getting a better result. In his next cases he excised still less, and did not get good enough motion. He said that he could not succeed in striking the happy medium. He did not see the necessity for removing the lateral ligaments.

Dr. Gibney asked about the use of formalin in complete ankylosis of the joints with bony union. He thought Dr. Murphy was right in taking out all that could be taken and covering the bone completely with the flaps.

Dr. Cook said that where there are two extremes there must be a mean, and he felt sure that Dr. Davis would finally succeed in striking it.

Dr. Murphy, in closing, said that he had a positive conviction that he could produce a practically perfect, freely movable joint, because he had done so. He did not dare to leave the lateral ligaments in, and he felt that what he did leave was enough to insure good motion. In cases of gonorrheal infection he did not follow out a different procedure from that employed in other cases of bony ankylosis. It was only necessary to avoid infection of the joint.

Paralysis of the Shoulder, with Especial Reference to Its Mechanical Treatment.—Dr. David Silver of Pittsburg first considered the relative frequency of paralysis of the upper extremity, and the reason for the regression of the paralysis in the arm and for its more frequent persistence in the deltoid. He reiterated the principle of relaxation in the treatment of paralyzed muscles, and described its application to the shoulder by means of a simple and comfortable appliance. Cases treated by this method were reported and photographs of them exhibited.

Presentation of Apparatus.—Dr. Phil Hoffman exhibited a modified osteoclast; and Dr. Compton Riely, a new osteoclast, a safety paralytic knee-brace lock, a combination clubfoot shoe and brace, and a clubfoot brace.

Dr. Little exhibited drawings of his osteoclast, which he had not brought with him.

Dr. Ridlon criticised all three osteoclasts and said that he preferred the Gratin.

Dr. Ryerson said that with the lever osteoclast one was liable to keep on pressing after the leg has been broken, and to push the fragment through the skin.

Dr. Wilson was pleased with the Little osteoclast, which he considered the simplest, most efficient, and easiest to manage of any he knew of. He would not use it for adult bones, however.

Dr. Hoffman said he had used his instrument five years. He said that the bearings of his osteoclast were as strong as those of the Gratin, and that it would break bones as easily. It was the other parts that were lighter, thus making his instrument portable. It was much simpler than the Gratin, and could be taken apart and cleaned. It was also much cheaper.

Dr. Riely said that the lever of his osteoclast could be released instantly. While it might be a little trouble to place the leg in the rings, there was no danger of its being caught there.

Operative Treatment of Intracapsular Fracture of the Hip Joint.—Dr. C. G. Davis of Philadelphia reported three cases in which, by open incision, the edges of an ununited fracture were freshened, and then the limb was put up, in the abducted position, in plaster of Paris. The result in the first two cases was good. The third patient could walk without support on her discharge from the hospital, but subsequently had an attack of rheumatism in the operated leg, requiring her to use crutches.

Dr. Wilson said that he had reported a case in which a nail had gone further than he intended, and had penetrated the acetabulum without causing any alarming conditions. He thought that this result must have been the reason for his success in other cases. In the case reported the patient was so pleased with the result that she refused to have the nail removed. He had not intended the nail to be so long, but had miscalculated, not having allowed for the pushing of the separated fragments together in the process of driving home the nail.

Dr. Stewart L. McCurdy of Pittsburg said that if the nail was within the capsule, and if the force used had been considerable, the ligamentum teres would be injured and its nutrition destroyed, the nail remaining in the joint as a foreign body. He had removed the nail in three cases in which this had happened and caused great pain. The patients all made a good recovery.

Dr. Peckham wondered whether it would not be a good thing to make the nail purposely long enough to go into the acetabulum.

Dr. Willard described a screw invented by one of his assistants. The screw part was made of ivory and the head of brass. The head was removed and the ivory subsequently became a part of the bone.

Surgery of the Motor Peripheral Nerves.—Dr. Alfred S. Taylor said that the application of surgery to peripheral nerves was based upon the power of nerves to regenerate, the power of one nerve to assume vicariously the function of another nerve of the same type, and the persistence of muscle for the regenerated nerve to act upon. The time that had elapsed since the onset of paralysis was of variable importance, while the condition of the paralyzed muscles was of prime importance. Accessory factors influencing the results were contractures of muscles and ligaments and undergrowth and deformity of bones, especially at the joint ends. He described the technique in end-to-end suture (nerve-crossing, if necessary), various methods of lateral anastomosis, and bridging and transplantation.

Dr. Ryerson did not think Spitzy's method of nerve transplantation very rational; and he considered Murphy's procedure very dangerous. He did not feel that one was justified in taking off healthy nerves to attach to a diseased one. He suggested the use of the dog's artery instead of catgut in the brachial plexus cases.

Dr. Charles E. Thompson of Scranton, Pa., said that he always employs catgut in his work. He described an operation done for nerve injury in each of five cases. The result in four of these was very satisfactory. The fifth was a case in which the spinal cord had been completely crushed. Dr. Thompson freed the two nerves on each side and traced them out along the ribs. He then drew them in, passed them down, and united them to the nerves below the injury. Nothing of the ultimate result could be known because the man died of an abdominal injury received at the same time as the injury to the cord.

Operation for Burn Scars.—Dr. Stewart L. McCurdy of Pittsburg described this operation, which consisted in extending cicatricial bands across joints by splitting them along the crest from end to end, and cutting to the right at a right angle from the end of the first cut, and to the left at the other end. The flaps thus made were dissected loose from the deep tissues. As the contracted portion was extended, the angles of the flaps dropped into the corners left by the end or right-angle incision.

Etiology and Treatment of Lateral Curvature.—Dr. P. W. Nathan stated as his conclusion that abnormal weight-bearing could not be the cause of spinal deviation. Static conditions were never responsible for organic or structural lateral curvature. These were caused by a distinct pathological process, which appeared at puberty and, after running a definite course, disappeared and left the spine deformed. After the disease had run its course, the deformity was incurable, although the posture might be improved.

Dr. McKenzie said that he had seen a well marked case of lateral curvature in an infant.

Dr. Lovett said that other statistics than those used by the author of the paper showed that a great many cases of lateral curvature appear before the age of ten years. He suggested that the condition may follow empyema, the curvature being to the sound side of the chest, and may also follow infantile paralysis of the muscles of one side of the back. He thought a great many curves were due to structural causes.

Dr. Sherman said that he had written a paper a long while ago, stating his view that scoliosis was due to a condition in the bone, probably rickets. This would give a basis for the structural change, followed by the definite deformity.

Dr. Nathan, in closing, said that the statistics quoted had merely confirmed his own findings. He admitted that empyema and infantile paralysis did sometimes produce scoliosis. The remainder of the cases that were not plainly due to rickets he considered to be those that came on before adolescence and immediately after puberty.

Saturday, June 6—Third Day.

The Mechanics of the Shoulder Joint from an Anatomical Point of View.—Dr. Joel E. Goldthwait of Boston said that the erect position of the shoulder was that of greatest stability, there being from 50° to 60° less motion in the rotation of the humerus in the glenoid cavity than when the shoulder drooped forward. In the latter position the lesser tuberosity of the humerus rested against the coracoid process, which was not above the head of the bone, but in front of it, in this droop shoulder position. This led to irritation at the point of pressure and to inflammation of the coracobrachialis bursa. The restriction of motion at this point that such an inflammation caused, with the change in the angle of the pull of the long head of the biceps tendon, favored and made easy displacements of the head of the humerus.

Dr. Riely said that he had noticed a click in his own shoulder on leaning forward, and was glad to have heard an explanation of it. He asked whether Dr. Goldthwait would advise its being operated on.

Dr. Albee referred to two cases of dislocation of the shoulder in young men, upon whom he had operated by a modified Burrell's method with satisfactory results, neither patient having had any recurrence of the dislocation.

Dr. Arnold had observed that when he had tried to relieve the shoulder from weight-bearing by putting it in a high sling the patients had had more pain than when the arm was hanging down. He was glad to have heard the explanation.

Dr. Goldthwait said that in writing the paper he had had in mind the ordinary spring-back brace. He believed that the ordinary position in which surgeons place the shoulder after traumatic dislocation was not the best position, being equivalent to the forward position of the shoulder. The arm should be tied to the side and rotated outward at a right angle. He said that subdeltoid and subcoracoid bursitis were frequently associated, but that often there was no subdeltoid bursitis. His opinion about Dr. Riely's "click" was that if the condition should go further, so that he could not get his shoulder back, operation would be advisable. The treatment in subdeltoid bursitis, he said, was the same as the treatment of any other bursitis. When an operation was performed, if the patient was not naturally erect, the surgeon should insist upon the shoulder being thrown back.

The Occurrence of Anterior Poliomyelitis in Massachusetts in 1907.—Dr. Robert W. Lovett gave the result of an inquiry addressed to every physician in Massachusetts, asking for a report of the cases seen in 1907. An analysis of 238 cases reported, with regard to distribution, time of occurrence, evidence of contagion, and other factors bearing on etiology, showed that the data obtained pointed to separate foci of infection, with transmission to neighboring towns.

The Necessity for Early Orthopedic Treatment of Poliomyelitis.—Dr. Wisner R. Townsend of New York stated that the majority of cases of poliomyelitis were followed by deformities, practically all of which could be prevented by appropriate treatment. They might occur very soon after the attack. Orthopedic treatment was desirable from the beginning. Statistics were given of the deformities occurring within eight months after the epidemic in 1907 in and around New York City.

Dr. Townsend said that he had never seen one genuine case of complete recovery. The cases in which recovery had been pronounced complete were those in which there had been marked depression and the paralysis had not been relieved, although this weakness had been improved.

Dr. McKenzie described an epidemic of the disease in Canada in 1905 or 1906. He had seen none of the cases during the attack; but the conditions in those that he had seen afterward were similar to the conditions ordinarily following infantile paralysis. He knew of two families having three children each left badly crippled by the illness. In the treatment he laid a great deal of emphasis on education. He cited at length a case to show the effects of educating the child gradually to use apparatus.

Dr. Ridlon said that he had seen during the last four years several cases of anterior poliomyelitis in adults, and he thought that care should be taken not to overlook its symptoms when they appeared in older persons.

Dr. Arnold said that the late epidemic of poliomyelitis had been felt in Connecticut also, where the same phenomena were noted as in Dr. Lovett's cases. He said that the disease also occurs epidemically among dogs, cats, and chickens. He had seen cases of complete recovery, especially in chickens. These epidemics usually occurred in the fall, and wet seasons were prone to bring them about. He suggested the use of these animals for the purpose of studying the pathology of the disease. As a transition between complete rest and putting the child on its feet, he suggested exercise on the floor.

Dr. Sherman referred to the use of electricity in such cases, and said that he regarded it as merely a means of irritating the child. He had always succeeded in getting a fair idea of the child's power to use the various muscles by tickling it or by picking its foot with the end of a match, in order to get it to try to use the muscles. He did not see how faradism to the muscles could affect the condition of the spinal cord, which was the seat of the disease. He suggested that pediatrists should always, when called in to see a sick child, test its power to use its muscles, as well as examine its throat.

Dr. Peckham was in sympathy with Dr. Townsend's plea for orthopedic treatment of these infantile cases, as well as with Dr. Sherman's views regarding electricity. He had quite given up the use of the latter.

Dr. Little said that his experience in England was also that the commonest history in such cases was that the child had gone to bed well and awakened paralyzed.

Dr. H. L. Taylor said that a careful examination of the voluntary power by a competent orthopedic surgeon would usually prove more useful than a report of the electrical examination by a neurologist. He himself had received reports of this kind absolutely misleading in the light of the clinical examination. He had found treatment to be absolutely harmful during the attack and for the first two months afterward, and to be absolutely useless after that time.

Dr. Lovett said that his reason for writing the paper had been to call the attention of the general practitioner to the inquiry, thus enabling them to recognize these cases better. He thought that the most sensible treatment would be to empty the bowels rather than to blister the spine. He thought that the disease was an intestinal infection with an anaërobic bacillus such as might be gotten through milk. He believed that the matter of partial paralysis received too little attention. A muscle might be either partly

or completely paralyzed, or simply stretched and disused. Between the stages of activity and paralysis there was a stage of slight weakness. He thought that more attention should be paid to voluntary attempts to move muscles and less to massage and electricity.

Drop Phalangette.—Dr. Walter G. Stern said that the essential lesion in this condition was a subcutaneous rupture, or an overstretching of the extensor tendon at or near its insertion into the distal phalanx. The deformity was produced by indirect violence, often slight. The power of active extension of the phalangette was lost, and the phalanx dropped down and remained flexed at a right angle. Passively, the finger could be fully extended. In three of his eight cases he had found it necessary to suture. The remainder were treated by splinting for six weeks. These were recent cases, operated on within a few weeks after the occurrence of the injury.

Typhoid Spine.—Dr. George B. Packard of Denver reported several cases.

Dr. John L. Porter of Chicago had found that patients who had left the hospital and returned later usually said that they had had pain in the spine since shortly after getting up. He believed that the severity of the condition was in proportion to the amount of inflammatory reaction. All his patients had recovered under the sole treatment of keeping the patient flat on his back.

Painful Feet of Raynaud's Disease.—Drs. H. Augustus Wilson and Charles H. Muschlitz of Philadelphia presented this paper, which was read by the former. They said that the painful feet of Raynaud's disease were of a peculiar character. The pains were symmetrical, worse in cold weather, easily affected by use, and not immediately relieved by rest; frequently the pain continued for a long time after the discontinuance of the function that had produced it. Characteristic bilateral gangrenous spots developed. The most trivial operative procedures were followed by nonhealing and sloughing. When the nails became loose the nail-beds sloughed more or less extensively if the nails were forcibly removed. Pressure apparatus of any kind was productive of sloughing and gangrenous spots.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City for the week ending October 24, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	509	156
Diphtheria	322	17
Measles	133	6
Scarlet Fever	129	2
Smallpox	—	—
Varicella	82	—
Typhoid Fever	84	16
Whooping Cough	26	1
Cerebrospinal Meningitis	9	6
Malarial Fever	—	—
Totals	1294	204

The Vegetable Diet and the Lactofarinaceous Régime in Dyspepsias, Chronic Gastroenteritis, and Convalescence in Infants.—Clemente Ferreira recommends the use of farinaceous preparations in several pathological conditions in infants. In dyspepsias and gastroenteritis we often find that milk is not tolerated. After the symptoms of fermentation have been relieved by the use of the water diet there comes a time when milk will not be tolerated, but will renew the trouble and protract chronic enteritis eternally. Here is the place where the use of vegetable and lactofarinaceous preparations is useful. These substances predigested in the oven act as protectives against fermentation when mixed with milk foods. They are most useful in milk intolerance, recovery from acute intestinal troubles, chronic intestinal troubles, and in the dyspepsias of weaning.—*Archives de Médecine des Enfants.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending October 23, 1908:

THE DEVELOPMENT OF THE LEGAL RELATIONS CONCERNING THE INSANE, WITH SUGGESTIONS FOR REFORM.*

By ALLAN McLANE HAMILTON, M.D., F.R.S.E.,

NEW YORK.

ONE OF THE CONSULTING PHYSICIANS OF THE MANHATTAN STATE HOSPITALS FOR THE INSANE; FORMERLY PROFESSOR OF MENTAL DISEASES IN THE MEDICAL DEPARTMENT OF CORNELL UNIVERSITY; PRESIDENT OF THE NEW YORK PSYCHIATRICAL SOCIETY.

The object of this lecture is to point out the present disharmony between advanced psychiatry and the law, and to call attention to the dry-rot of medical jurisprudence so far as it relates to provisions for the proper commitment or liberation of insane patients, as well as to matters of responsibility and capacity. I would at the same time urge certain reforms in the direction of providing methods of relief, and an adequate and impartial expert system.

In this connection two great problems present themselves to our attention and will be considered to-night. The first deals with the justification of the inevitable restricion of liberty, and the retention and restraint for treatment against the patient's will or choice. The second implies the consideration of diminution or abolition of personal capacity and responsibility by reason of mental disorder.

The former must comprehend the determination of liberty, and therefore a consideration of the individual's rights, and at the same time a reference to the unsettled state of public opinion in regard to mental disorder in general, and what should be done. I shall also refer to the special indications which have to do with the sequestration of the patient. In this connection we are confronted with the popular and general prejudice among ignorant people against hospital treatment, for every one at all familiar with the commitment of insane subjects must know that institutions of this kind are generally regarded only as prisons in which persons are immured after being kidnapped, and that even among some of our judges there is often a disposition to look upon detention in pretty much the same way as they would the infliction of a sentence for wrong-doing, and they are consequently over-cautious. For a long time, and at present, more has been thought of the general safety of the public, and greater attention has been paid to the demands of cranks or ex-patients than to the actual need of the patients themselves. In fact much injudicious and oppressive legislation is due to the agitation of manifestly insane persons who have found the ears of law-makers and reformation societies. Personally I have known of numerous instances where sincere psychopathic patients, replete with delusions, have made untruthful assertions to sympathetic listeners, and it is against this that we have always to be on our guard and to act.

This very making of drastic laws has led to frequent collisions between medicine and law, and it is to be hoped in the future that some form of legislation will supplant that at present in general operation, and the attitude of those who have to deal with the commitment of patients will be rather what Dr. Meyer very happily calls a *reinforcement* of *persuasion* than an arbitrary or punitive action, as it is so commonly supposed to be.

Again, if the community is made to understand that insanity is, after all, a disease like any other, the provision of a temporary method of examination or special quarantine will be accepted as a matter of course, and the patient shall suffer no stigma or disgrace.

In regard to the discussion of the first part of the subject, we find that an appeal to the law, either for the commitment or discharge of patients, is about the first thing that is usually considered, the result being the infliction of a great deal of unnecessary injury to the subject in the way of court proceedings and newspaper publicity. On the contrary, the case of each patient should be first considered by the physician who attended him, in co-operation with those of the asylum to which he is to be sent, and perhaps the State Commissioner in Lunacy, and the latter should be given more power than that with which he is now invested.

The *second* problem, from its very nature, is one of the greatest importance, for it implies the definition of irresponsibility as the result of the insane condition, the consideration of the acts of the manifestly insane, and those which are insane in themselves; the determination whether there is any such thing as absolute responsibility or absolute irresponsibility; a history of the tests of insanity, and their evolution, and whether such tests as have been hitherto used are sufficiently adapted to our better knowledge of to-day.

It will in this connection be seen as well that the new psychiatry has much to do with the modification of our previous ideas regarding the value of testimony and capacity of every kind.

In connection with these two matters our relations with the law are concerned first in the *commitment* of patients, which varies in different states, the preliminaries consisting in either the examination of the alleged lunatic by one or two physicians who make a certificate which is approved by a judge of a Court of Record, or in other states by the testimony or the presentation of affidavits by one or more physicians, in con-

*Delivered at the New York Academy of Medicine under the auspices of the New York Psychiatrical Society.

junction with the next of kin or a self-constituted guardian, and it is requisite that the subject be brought before the judge or jury, unless the latter agree that it is unnecessary because of his condition or the harm it may do him to appear in court. His *removal* from an asylum may consist in the fact that he is either discharged as "cured" or "improved," or he may be allowed to depart on parole, or the ordinary process of *habeas corpus* may be invoked, when he may be either examined by a justice and commission, or, should there be a question of his property, the matter is left to the sheriff's jury. Despite the contention of sensationalists, there are ample laws which, if observed and enforced, would give him while detained the fullest liberty to appeal to the authorities who may be the Governor of the State, the State Commissioner in Lunacy, or any person occupying a judicial position. So far as his written communications are concerned they must be sent either to his family or to the State Commissioner at Albany, and if they are coherent should receive due attention. Of course it will be seen that the responsibility of the superintendent of an asylum is very great, for many of his patients are apt to deluge the mails, if permitted, with incoherent, obscene, and meaningless letters.

As far as my experience goes I do not believe that any patient is ever deprived of the right of appeal, or is ever wrongly kept in an asylum, and with the present careful system of inspection and study upon the part of the State Commissioner in Lunacy and his assistant, and by the physicians of the asylums themselves, no unjustly detained person is likely to escape the notice of these officials. Reference to the reports of the State Commissioner in Lunacy and the Insane Pavillion at Bellevue shows that a very small number of people are improperly committed, or even find their way to the State hospitals. This is the more extraordinary considering the difference of opinion as to what constitutes insanity.

The second problem, as has been said, deals with the impairment of personal capacity and responsibility by reason of mental disorder, and we are at times called upon in various matters of a civil and criminal nature. These legal measures include first the appointment of commissions or committees, and the establishment of guardianship, again matters of capacity so far as the making of contracts by the insane, and their *torts* are concerned, the latter word being used with reference to the malicious acts which persons may indulge in as the result of their mental infirmity, and these may possibly consist in trespass, injury to others, or destruction of property, and other acts which would render a sane person liable to a suit for damages. The contracts naturally may be of the most varied character, and the excuse of incompetence by reason of insanity is often urged as an invalidating factor either by a person who recovers and then seeks to avoid the disastrous consequences of a bargain or sale he has made, or the existence of previous insanity may be urged for the purpose of the annulment of marriage or procuration of divorce. Then again, the psychiatrist is often required to give evidence in regard to the testamentary capacity of those who make wills.

In the matter of the *probation of wills* the attitude of the law is exceedingly unsatisfactory. The two invalidating factors of a will that are generally recognized are the existence of delusions directly relating to the testator's knowledge of the objects of his bounty, and the nature and extent of his possessions, and the law holds that even though a man may be insane and have pathological delusions of various kinds, so long as these do not relate to the two conditions I have mentioned, he is held to have disposing power. The decedent a long time before his death may have even harbored delusions of a systematized character, but so long as they were not directly germane to those who had a right to his consideration, or would prevent him from knowing what he was giving away, his will has been upheld. The existence also of a more or less profound dementia has invalidated such instruments by showing that the testator had not enough power to resist the importunities of others, or that he was, in the eyes of the law, *non compos mentis?*

No one familiar with the disposal of these cases has not at some time witnessed the effect of the recital of a variety of eccentric or credulous acts which have been attributed to an ignorant person, and which have influenced the surrogate or jury to upset a perfectly reasonable and equitable will. In the contest of the will, especially of an old and weak person, the door is opened for the testimony of the ignorant or those possessed of cupidity, who are as apt as not to urge the unconventional acts of an otherwise sane and disposing mind as evidences of insanity. The pity of it all is that the surrogate or jury, who are not judges of psychopathic disorders, are the sole arbiters of what constitutes true mental derangement, and as the law is now constituted there is no adequate appeal.

In criminal matters insanity as a defense is too familiar to at this time need further reference. Not only in civil but in criminal proceedings are we to gauge the defendant's alleged irresponsible condition, but we are to determine the amount of responsibility, and whether, as Mercier puts it, he is "rightly liable to punishment"; to pass judgment upon the worth of the testimony of such a person, and it is even sometimes our duty to investigate the unfitness of a juryman who becomes insane during the course of the trial, as has happened several times in my experience.

Before finally and directly passing upon the matter of insanity as a defense, the alienist may be required either as a member of a *commission* or as an expert to determine whether the indicated person suffers from a mental disorder which will prevent him from properly communicating with those who are to defend him.

In regard to the latter there has been a growing conviction among those concerned in the care of criminal lunatics that the machinery for their disposal is inadequate. It has been the custom, at least in this State, when a person is under indictment and is thought to be insane, for his own counsel or any citizen to move for the appointment of a commission for the purpose of determining whether he is at the time of unsound mind. This commission is appointed by one of the Supreme Court justices, or a judge of one of the lower Criminal Courts, and consists of a lawyer, a layman, and a physician, who are to listen to witnesses and eventually make a report to the judge who appointed them. It will be seen from the constitution of this body that the doctor is always in the minority, and it is often that he is out-voted because his fellow commissioners are inclined to take the popular and hazy

view of what constitutes insanity. Although he is empowered and expected to conduct such an examination as he may see fit, this proceeding makes him in a measure a witness instead of a judge, for he has to explain to his colleagues the significance of the answers he receives or the meaning of the prisoner's actions. This form of procedure sometimes leads to the greatest miscarriage of justice through prejudice, political leanings, or sympathy with the indicted person, and it can readily be conceived how a malingerer may be sent to an asylum until the public excitement has subsided, when he is to be tried for the crime itself. The decision of the commission at this later date may be utilized by the prisoner's counsel, and then has much to do in the way of mitigating the original offense, if not securing an acquittal.

It is to be regretted that under the present system the State Commissioner in Lunacy is permitted to testify as an expert in court, and he is often chosen by one side or the other because of the weight attached to his official title. No matter how fair-minded and honorable such an official may be—and so far as my experience is concerned the incumbents of the office have usually been men of standing and integrity—it must be seen that the position of Commissioner after he has given his testimony *pro* or *con* must be an exceedingly delicate one, as the adjudged lunatic may be committed to an institution which he visits, and as it is his duty to recommend the discharge of sane or recovered patients, it may be conceived in what an awkward dilemma he is placed if he has committed himself on the witness stand, especially if his testimony be to the effect that the person is not insane.

In this connection reference may be made to the abuse of confidence where a physician or an expert may disclose information obtained in confidence. In the case of The People versus Hoch it was held by the Court of Appeals that "The examination by a physician of a person accused of crime at the special employment of people for purposes of prosecution, is not the attending physician of the patient in a professional capacity, and the physician is not rendered incompetent on that ground to disclose information acquired by him in such examination."

While this decision is undoubtedly strictly true and in accord with the law, it may be seen how a disingenuous and prejudiced examiner may pump the prisoner or become the same as any other witness for the prosecution if compelled to testify. When such a physician couples his testimony with that of a general expert character, which is injurious to the prisoner his attitude is a highly dangerous one. Under these circumstances the attitude of the prosecution's expert is as a rule open to the criticism of unfairness and partisanship, and it may be seen how a dishonest man may deny to the suspected person the fair play to which he is entitled, and this is certainly an argument for a neutral board of expert examiners, whose opinions shall be founded upon the conduct of the prisoner, and who shall decide whether he is responsible or irresponsible. In other words, the physician should not be asked to be a detective whose opinion has been developed with guilt in view.

Before proceeding further something may be said about the development of the legal consideration of insanity, and it is hardly an exaggeration to say that little or no change has taken place in the legal estimate of insanity since the days of Lord Hale or Sir Edward Coke, more than three hundred years ago. To say the least, there has certainly been a disproportionate advance when we recognize the strides that have been made in the field of mental medicine. For some inscrutable reason there seems to have been tardy reluctance upon the part of our sister profession to abandon the old idea that existed so long ago that in reality there was but one form of insanity, and that essentially hopeless and continuous: in other words, that the unfortunate subject was in the beginning bereft of his senses or reduced to the level of a brute or wild beast, to be shunned or avoided generally and to be denied all consideration.

In the meantime the study of mental disease has made astonishing advances, and with this we now find that the insane are not merely incarcerated, but intelligently treated. But we still find ourselves hampered somewhat by the inadequacy of the laws and provisions for the proper control of people mentally afflicted, and there is yet no legislation that will enable us to keep non-committed people under observation for more than the present five days, so that it may be determined whether the real malady is one of a temporary nature and better treated in a so-called psychopathic hospital, or sent to a regular asylum.

It is also to be regretted that proper provision has not been made for those whom Bianchi calls *the delinquents*, especially the very young who have criminal tendencies in connection with a form of congenital imbecility. Intelligent care and discipline are needed under these circumstances for the children of the rich as well as the poor, and correctional schools are a vital necessity. As it is to-day, vagabondage, dishonesty, precocious sexual vice, and other early evidences of immorality that are the product of a high-grade imbecility or other defective condition, are not dealt with until the subject is brought into the children's court, or his crime leads to his incarceration in the Elmira Reformatory, the chance being that the evolution of criminal tendencies without restraint for so long a time has terminated in habitual criminalism.

In this connection attention should be called to the large number of paranoiac insane who have been improperly discharged from institutions, or in the past those who have not even found their way there, and are always a menace to the community. Greater supervision of these people is urged upon the city magistrates, for my own experience convinces me that every year numerous prisoners who are sent to the workhouse or penitentiary for short periods of time should rather be given the benefit of asylum treatment and discipline, as they are undoubtedly irresponsible, and belong to the large class of congenital psychopathic degenerates.

I would also urge an improved paternal system and the appointment of visitors or special guardians who shall directly look after the committed person's interests, even where there is no regularly appointed committee of the person, as this class are as a rule poor and have no friends, and their little savings are misused. The time of the State Commissioner in Lunacy and his assistant certainly does not allow them to take the intimate interest that is needed in all patients, and it is for this reason that I would urge a semi-judicial board of active visitors, the members of

which shall be approved by the superintendent of the asylum and the State Commissioner in Lunacy; or an outside board or association may act in co-operation with the Hospital Staff.

The French law provides not only for the voluntary commitment of patients, but for a mode of surveillance of these commitals, while both in France and in England, if an insane person is taken care of at home, he is regularly visited by the authorities, and if in a private or public asylum, he is represented by a provisory administrator, who recovers the sums due to the patient, pays his debts, gives bail, which may not be longer than for three years, and he may even, by virtue of special authority, granted by the president of the civil court, sell the patient's furniture and other effects for his benefit. This administrator in a measure compares with the "guardian of a person" appointed by our sheriff's juries and courts, but there is none of the involved machinery of our system in vogue, and none of the great expense.

The American laws in regard to *divorce* and *marriage* of the insane are in the present shape exceedingly unsatisfactory, and as a rule the Courts are simply guided by the rules of common law. The interposition of insanity, as it is in ordinary contracts, as a factor in the annulment of marriage and the procurement of divorce, is differently considered by many States, and one of them, Florida, afterward repealed a law of this kind that had been made to suit certain temporary exigencies. There seems to be a disposition to regard post-nuptial insanity as a valid cause for divorce, but this appears to be to the writer a brutal excuse, for there is no reason why a man should not take care of his afflicted wife after her marriage just as much as if she suffered from tuberculosis, cancer, or any other physical disease. On the other hand, the laws are lax and variable regarding the failure to apprise one of the contracting parties to the marriage of the previous insanity of the other.

Legislation should be invoked now that our knowledge of the psychoses is so different from what it was even a few years ago, for we now know the importance and possibility of a return in such afflictions as *circular* and *manic-depressive* insanity, and there should be no concealment of the previously existing psychosis upon the part of the contracting parties to the marriage, or on the part of their parents or physicians, through any motives of false shame. If found to be of a deteriorating or recurrent type, its consequences should be pointed out so that an intelligent agreement could be made if the contracting parties chose to take the risk. It is not, however, to be assumed that there is always a deliberate attempt at deception, for many people uneducated in psychiatry may even regard what may be serious periodic seizures as some temporary autotoxic or exhaustive psychosis or some temporary affection.

The experience of a good many years has impressed me with the horrible consequences of this kind of concealment upon the part of worldly or inconsiderate parents, and I have known of several young people whose lives have been wrecked by the espousal of a mate who had presented, previous to the marriage, one or two attacks of periodic trouble, and whose malady later advanced in the conventional way. It is needless to say that the insane person is usually ignorant of the importance of the pre-nuptial psychosis, but the real persons to blame are the parents. At some future time the attention of legislative bodies will undoubtedly be directed to this matter, just as they are to tuberculosis in some of the western States, and the day may not be far distant when the matter of bad heredity may either be made a bar to marriage, or may be properly urged in plea of separation or divorce, if for no other reason than to prevent the perpetuation of a diseased stock.

In the consideration of the laws relating to insanity, we come now to another branch, and that concerns the attitude of the courts in regard to criminal and civil matters where the question of unsoundness arises regarding the individual and his responsibility. I have elsewhere referred to the reluctance of the legal fraternity to avail themselves of the teaching of psychological medicine. Without going into history I may call attention to the fact that as late as 1723 there was no standard of responsibility, and even then Lord Onslow held "that it was not every kind of frantic mood or something unaccountable in a man's actions that points him out to be such a madman as is exempt from punishment. It must be a man who is totally deprived of his understanding and memory and does not know what he is doing any more than an infant or a brute or a wild beast. Such is never the subject of punishment." This way of considering responsibility remained in force until the year 1800, when Hadfield attempted to shoot King George III. in Drury Lane Theatre, when Erskine first laid down the doctrine of delusion as the real test of mental responsibility, and twelve years later, in the Dillingham case, it was held that, though a man might be incapable of transacting his ordinary business affairs, he must also be so influenced by his disease as not to know the difference between right and wrong. This was the beginning of the "right and wrong test" which for a long time, and even to-day with many jurists, simply implies the ability of the arraigned individual to have what might be called a technical knowledge of right and wrong —that is, for instance, that murder is forbidden by law, and that the punishment is death; but slowly, and after a long space of time, other qualifications have been added to the definition of irresponsibility, so that the element of want of control, the inhibition of will power, or the influence of specific delusions pertaining to the crime, have come to be regarded as exculpating factors.

About twenty-five years ago the writer, in the Liebküchner case, in which a woman poisoned her children under the influence of a delusion, made the distinction between a recognition of an *abstract* right and wrong, and the abolition of the applied or personal appreciation of the character of the act through disease and delusion, and the patient was sent to Matteawan, but even to-day there is a disposition to insist upon the antiquated test. In the first trial of Thaw a number of experts retained by the District Attorney certified that the defendant "knew the nature and quality of his act, and that it was wrong," and subsequently expressed it as their opinion that he was insane and paranoiac. Not only must we all be concerned with the impropriety of a medical man taking upon himself to say what constitutes "legal insanity," but we must deplore that kind of "fencing" which prevents the expert witness from admitting that a delusional lunatic

may have a clear knowledge of how an *insane act* is to be performed and that it is technically illegal. In this case medical jurisprudence took a great step backward.

On the whole, however, much progress in the matter of the humane consideration of the irresponsibility of insane people has been made in this country, and many of the courts have shown a tendency to coöperate with our own profession. Recognizing the influence of disease in destroying self-control, in 1844 Chief Justice Shaw, in the case of the Commonwealth versus Rogers, and in 1874 Chief Justice Perly, of New Hampshire, in the case of the State versus Pike, made decisions which illustrate this progressive tendency. It was held in the former case that "a person is not responsible for any criminal act he may commit if, by reason of mental infirmity, he is unable to distinguish between right and wrong in regard to the particular act, and of knowing that the act itself would subject him to punishment; or has no will, no conscience, nor controlling mental power; or has insufficient power of memory to recollect relations in which others stand to him and in which he stands to them; or has his reason, conscience, and judgment so overwhelmed by the violence of the disease as to act from an irresistible, uncontrollable impulse." In the second case Chief Justice Perly charged the jury among other things as follows: "You have only to consider, first, whether the prisoner was laboring under a mental disease, and secondly, such being admitted, whether the acts in question were the offspring of that disease." This seems to be a succinct and strong statement of irresponsibility, and if followed would avoid much of the hair-splitting conflicts which in the end usually involve a theological or metaphysical discussion and leave the jury in a hopeless condition of uncertainty and confusion.

One of the important tests of responsibility, as we all know, is delusion. While false beliefs may be entertained by sane as well as insane persons, of course the former have little or no weight. An ordinary false belief, or one that can be removed by proper evidence, is therefore not likely to be necessarily associated with a condition of insanity, although very often it is rather hard to draw the line between healthy and morbid false beliefs. On many occasions those of us who go upon the stand are asked whether the delusions of certain religious sects are not pathological, as, for instance, the belief in the immaculate conception, the miracles of the Bible, a belief in spiritualism, or even of Christian Science. Of course, preposterous as we believe some of these to be, it cannot be denied that they are held by a large number of good people who are not insane. There is undoubtedly, however, at times, no sharp dividing line between beliefs of this kind, which many people hold to be false or illogical, and those that are essentially abnormal. Putting aside those of the first class, which are sometimes what may be called autodelusions—in other words, erroneous ideas developed and nurtured by the individual himself either as the result of teaching or faith, or because their adoption leads to material and spiritual benefit and comfort, the ordinary false belief may form the *quasi* substantial basis of a distinctly insane delusion, such, for instance, as when a religious man sincerely believes he is commanded by God to kill some other person, or to do some erratic act, or, as has been the case, a man wishes to commit suicide, and, believing it to be a sin, has murdered another person that he himself might be executed by the authorities.

An insane delusion really is a "false belief which exists only in the disordered imagination of the individual," and which cannot be removed by the presentation of sufficient proof. It has by some been more simply defined as a false belief which is the result of disease. It is to be regretted that so far the law concerns itself solely with the pertinency of such delusion to the act in question, when after all it ignores the general disturbance that leads to the formation of this opinion, and the important truth that there are never actually limited delusions, but at some time or other the one in question may be simply a link in the chain of a far-reaching disorder.

The same narrow and hoary views as were held regarding Criminal Insanity as a defense in crime, have been upon the statute books from the earliest times, and are referred to to-day in civil matters.

Can anything be more untrue and illiberal than the antiquated statement in Chitty on Contracts, which is also held by Cowles and Bracton, that it is a well-established rule that a deaf mute cannot make a gift because he cannot express his consent to a gift, and for the same reason a lunatic, or any person of unsound mind, unless he enjoys lucid intervals, cannot make a gift. Again, that a lunatic cannot transact *any* business because he cannot comprehend the nature of the transaction. And still more incredible is the arbitrary legal claim that it is manifest at the outset that idiots and lunatics have no mind and cannot be said therefore to agree in mind in the sense necessary to form a contract."*

Happily this ironclad dictum is not taken literally, for there is a constantly increasing tendency in the way of liberality, to segregate insane acts and to analyze the mental disturbance of the person so as to determine at the time what may be his exact capacity, although there are many jurists, and even members of our own profession, who still believe that if a man suffers from a psychosis, his capacity and responsibility are absolutely abolished in all directions. The term "lucid interval" has been abused by the courts, for it cannot be accepted that any well-established insanity, can be characterized by periods when the mind is absolutely healthy, although to a layman this may be apparent; but as I have said, it should not follow that an insane person may not know the nature and quality of many acts.

When mental disease is studied from the purely psychological standpoint there may be a more rational *rapprochement* between the jurist and the doctor in regard to the conservation of certain faculties, even when there is much general psychic disorder.

Proceeding upon lines which have been in vogue from time immemorial, the terms of our justices are consumed with trivialities, the pockets of our clients are depleted to an unnecessary degree, while in these days of disreputable journalism their affairs are given publicity which can only bring unhappiness and misery to the alleged lunatic and his family, and can do no other good than to gratify the vulgar curiosity of the idle and ignorant. To those familiar with the great trials in this city and elsewhere where insanity is urged as a defense, there must be nothing but disapprobation of the protracted and

*Ordronaux, p. 299.

sensational conduct of capital cases which, as a rule, degenerate into a war between experts and so-called authorities, and where the prosecuting officer or his opponent, as a result of cramming, indulge in a profitless battle of words and crude psychiatry.

Usually upon the testimony of more or less ill-informed or prejudiced people, one side or the other frames a hypothetical question which, judging from its effect upon the experts and the jury, may really be denominated, as it was the other day by an alderman, as a "hypnotical" question. The lawyer, with little or no knowledge of insanity, crowds into this many alleged incidents which have no bearing whatever upon the conduct of the individual so far as real insanity is concerned, and it is usually immediately pulled to pieces by the other side. And then again, we are all familiar with the evils of expert testimony. Even a good and conscientious man can be made to make himself ridiculous by adhering to the legal obligations to stultify himself by the consideration of an incongruous collection of statements. In this connection I cannot too strongly condemn the present system of taking such false experts at their own valuation, and admitting to the courts men who are utterly without qualification, who are ready one day to give "expert testimony" when a gynecological or surgical point is the issue, and the next to give learned opinions about psychiatry.

The difficulties encountered in approaching these matters are largely dependent upon the very rudimentary and insufficient knowledge upon the part not only of the courts, but of the want of familiarity of the general public with insanity, and the paucity of information contained in any legal book, or in the ordinary treatises upon medical jurisprudence. At best the latter content themselves with the classification of fifty years ago, and contain few if any of the representative and illustrative cases which have been reported from time to time, and which review the advanced legal requirements of criminal and civil responsibility.

The public ignorance of insanity is hardly to be wondered at, and, as a rule, there are only retained popular traditions in regard to what constitutes mental unsoundness. It would not be a difficult matter to have the State constitution so amended that inquisitions would be referred always to a commission and jury hearings abolished. Juries of all kinds are apt to be governed by prejudice and sentiment. This is notably the case when the sheriff empanels a petit jury from all sorts of undesirable people. In a recent habeas corpus case where an old woman with a delusional psychosis, who had been incarcerated for many years, came before such a jury, tha body found her sane and ordered her freedom, although a majority of the commission objected. A clever but unprincipled lawyer worked upon the feelings of five of the jury who were "veterans" by showing that "she had been good to the soldiers during the civil war."

In a recent case which was tried by Mr. Justice Truax, in which a paranoiac named Russell applied for a writ of habeas corpus and was given nearly a week and the fullest opportunities for stating his case. Although possessing what might be called the legal instinct, and the highly developed logical sense which goes with reasoning insanity, he gave ample proof that he was the victim of a very complex series of delusions of persecution and suspicion which had existed for many years. While acting as bookkeeper in Sing Sing prison, where he was confined many years ago, he discovered what he supposed to be an error in the accounts, and developed the delusive belief that the prison officials were guilty of theft. This grew into the fixed delusion that his knowledge of the guilt of others had brought down upon him their enmity—that they had tried to poison him or get rid of him so that they might remain unpunished. In consequence he made various charges, and, his insanity being recognized, he was transferred upon a later occasion to Dannemora. From this place he applied for various writs of habeas corpus, and when refused he accused the judges who denied his application of being in a conspiracy with the original criminals, and the Governor of the State himself was believed by Russell to conspire to silence or imprison him. A decent evening newspaper was found to seriously question his insanity, and the justice of the dismissal of the writ, and I have since learned that the expression of the writer of the article simply voices a widespread impression in regard to the case.

But again, our own profession is not entirely blameless in the matter of unsettling public opinion and creating distrust of expert testimony. I know of a case in which one woman was declared insane because she walked in the wet grass (following the treatment of Kneipp), and another sane, or "at least very nearly so," who declared that she was at the same time Queen Victoria, the Duchess of Kent, and the Duchess of Asturia, and, not satisfied with these female titles, she called herself Lord Baltimore.

One obstacle to harmony between courts of law, and those of us who go to court, is the *vagueness of certain terms* which find their way into legal and textbooks. I suppose more discussion has arisen in regard to what "unsoundness of mind" means than any other legal term. Then, too, the terms "idiocy" and "dementia" are often made by members of the legal profession, or held by the court to cover various psychoses with widely different symptoms, and where the influence upon the responsibility or capacity is most important. In country courts especially it is very common to find all insane persons called "demented," and while this is etymologically correct, it is clinically wrong. The advance in our modern study of mental disease has, in the last ten years, absolutely changed the groupings. It will be seen, therefore, that all our old use of terms, especially when we make use of historical cases reported in the language of the trial and legal decisions, and the older textbooks, is likely to lead us into much trouble and confusion.

More full legislation is certainly needed for the care and protection of the so-called *borderland cases* and of the *alcoholics*, for as the criminal law now stands there is a disposition to consider all people responsible who commit crimes as a result of drunkenness. Of course this is based upon the assumption that "men put poison in their mouths to steal away their brains," but here, again, we are often confronted with the existence of psychopathic states due to defective heredity, where at least some allowance should be made for the unfortunate inheritance. The prejudice against alcoholism as a defense really extends to the diseases known as acute or chronic alcoholism, and the only hope of the defense or for the establishment of incapacity or irresponsibility

is where, through a pronounced or continued toxemia or through structural alterations, mental enfeeblement or actual delusions are produced. Of course the difficulty of judging of the extent of mental enfeeblement in all these cases, as well as those due to drug habits, is very great, but we ought at least to recognize, as the French and others do, a limited responsibility or capacity. In criminal cases this is absolutely necessary, for there are not only many psychoses due to intoxication of various kinds, but hysteroid psychoses or states due to autosuggestion, where the extenuation is not complete; it seems, therefore, an injustice here again to apply the hard-and-fast rules of law which exact the arbitrary standard of right and wrong.

What we need is some legal cognizance of, and better measures for the protection of the community, in the vague cases where doubtful responsibility has led to the infliction of insufficient or unsettled punishment; or where the defendant, although believed to be mentally affected, is incarcerated in a prison instead of a criminal asylum. As an example of such a case I may refer to that of "Rousseau," the man who undertook to blow up the steamship *Umbria,* and who placed infernal machines and bombs beneath statues in Washington and elsewhere. A commission subsequently declared him responsible, although they were inclined to believe that he was "medically insane," whatever that may mean. He was sent to Sing Sing, where he now remains, with many others who are controlled as other prisoners are, but who will eventually be discharged. Of course when this occurs the community may suffer from some fresh act of violence or through the dangerous proclivities of the person whose insanity is so imperfectly recognized, and it really seems as if some subsequent espionage was a matter of necessity.

A provision recognizing the limited or partial responsibility has found place in the jurisprudence of most of the foreign courts, but not in our own or those of Great Britain. Legrand de Saulle has insisted upon the presentation of this as a defense, especially in hysterics, and where the psychosis does not imply the total extinction of the ethical sense through disease.

Von Liszt of Berlin has recommended certain measures for the management of individuals of limited responsibility which, though radical, are a decided advance in the right direction. If a person is declared not guilty because of irresponsibility, or if the full penalty is not imposed because of diminished responsibility, the Court is to fix a provisional detention and also to settle the guardianship. The following provisions are recommended:

1. Diminished responsibility with danger to the community demands a lesser degree of punishment.

2. Diminished responsibility with danger to the community demands mild punishment and detention.

(a) If a person is fit to be punished, the penalty is inflicted and the detention interrupted.

(b) If the prisoner is not fit to be punished detention is resorted to immediately and punishment is deferred.

The consideration of the justice of this is not to be gone into here, but Bleuler in criticising von Liszt's plan is of the opinion that it is open to objection because in some cases it implies retaliation.

In other countries greater harmony exists and the machinery of law is much more expeditious than it is with us. Under the English system no matter how insane a man may be, his technical guilt is established by the ordinary rules of evidence, and the consideration of the plea of insanity subsequently receives the attention of the expert sent by the Home Secretary. In Germany and France much more help is derived from alienists in a quiet way than it is here, and commissions with extensive powers settle the question. In France the medical man is prevented from expressing anything more than a full opinion of the purely medical side of the case and making a diagnosis. "He is neither judge, accuser nor defender, but it is the commissioner of police and the mayors in other cities who may order all necessary measures, supported by a doctor's certificate, with the understanding that within twenty-four hours a report must be made to the prefect, who, without delay, shall act thereon."

It seems to me that the first step in advance is an absolute change in the present *expert system,* and that as a substitute therefor experts should be selected by the Academy of Medicine and the Psychiatrical Society, or elsewhere by county socities; that the candidates should receive the approval of the Appellate Division of the Supreme Court upon the production of the necessary affidavits and endorsements as to character and experience, and that from this number appointments should be made at the instance of the trial judges, after conference with both attorneys. The person so selected should make a full examination, not only of all incidents of the patient's previous life, but of all the symptoms and the conditions that might enter into the disputed point. In fact, it should be in every sense a medical examination made by a doctor, and there should be no consideration on his part of the legal aspect of the case. Of course the right of cross-examination would be extended to the expert, who is really, after all, an *amicus curiae.* His compensation should be determined by a regular fixed scale of charges commensurate with his standing in his profession.

The action of the Supreme Court of the District of Columbia in the Schneider case is suggestive of what may be done to avoid a contest of experts.

The prisoner, after having been convicted of a double murder, with a plea of self-defense, was afterwards refused a new trial by the Appellate Court. It was alleged that he at this time began to manifest symptoms of insanity, and at the instance of Chief Justice Bingham and Justices Hagner and Cox, three physicians—of whom I was one—were invited to take testimony, interrogate the witnesses who had appeared at the original trial, and examine the prisoner.*

*An attempt in the right direction has been inaugurated by Justice Warren Foster of the Court of General Sessions of this city in the appointment of a medical commission to determine the mental condition of Charlotte Hitchcock, who killed her husband in November, 1907. Drs. Carlos McDonald, Frank W. Robertson, and the writer were chosen by the Court to take testimony and to report not only upon the condition of the woman at the time of the alleged murder, but at the present time, the purpose being to avoid the battle of experts which has been the feature of recent proceedings in the New York courts, and to take the matter away from a lay jury, who naturally know nothing about psychiatry and who have good reason to discredit all expert testimony when men of apparent equality in professional attainments swear diametrically opposite. If the report of this commission is to the effect that the woman is insane, she is to be committed to an institution, and if not, she is to stand trial in the ordinary way.

In criminal cases where the defense of insanity is urged, the indicted person should be sent to some public institution for the insane for three or six months to be absolutely under the supervision of impersonal observers and visited by the Court's expert, who should from time to time report. No injustice could arise from this measure, for certainly if the defendant were insane this kind of care would be a necessity under all circumstances. If he were feigning it could be readily detected and he would certainly be removed from any help in that direction, or from the assiduous attentions of a certain sensational portion of the press.

An observation law of this kind has been in successful operation for many years in the States of Maine, Vermont and New Hampshire, and within a year or two has been in force in Massachusetts.

In this connection I approach a subject in regard to which I do not wish to be misunderstood. That is the absolute disregard not only of person but of public rights by certain newspapers who are inclined to mold public opinion, perhaps not always deliberately, but in the course of procuring sensations for the idle and unthinking. It is all very well to speak of the so-called freedom of the press, but in several criminal proceedings of late this freedom has degenerated into license, in some cases leading to the hounding and conviction of individuals whose guilt was at least a matter of doubt, or who have been eventually acquitted after a dreadful experience in the death chamber; or, on the other hand, the release of clearly guilty individuals as the result of manufactured maudlin sentiment and misplaced sympathy.

They deal with these things more vigorously abroad, and I am familiar with a case which was recently tried in London where a sensational reporter, who had served his apprenticeship in this country, attempted to influence English public opinion in advance as to the guilt of the prisoner, and was promptly brought to the bar of the court and reprimanded by the Lord Chief Justice, the ultimate result being, as I believe, the passage of an act of Parliament which made it a misdemeanor to interfere in this way with the rights of the prisoner or anticipate the action of the Court. Happily in this country there has been an attempt to meet this evil, and in the Terranova case Mr. Justice Scott vigorously and courageously called attention to the misrepresentation on the part of one newspaper. If most of these cases were tried less publicly, with the exclusion of the photographers, and the sickening screeds of what are known as "lady journalists," there is no doubt that much mischief might be averted and public morality would not be debauched as it is at present. In one case in which I appeared I have no doubt that the defendant, an ignorant young Italian girl, through these agencies and through morbid vanity that had been engendered, had been really placed in a hysteroid condition and was unable to fully appreciate the gravity of her position and properly instruct her counsel. Certainly many civil cases in the nature of hearings, or where a commission is appointed to dispose of the matter, should be tried *in camera*.

In conclusion I may briefly recapitulate, suggesting certain measures and making the following recommendations:

1. There should be obligatory information of the commissioner in lunacy in regard to the existence of all cases of insanity.

2. Though the commissioner in lunacy may have power to license private institutions, he should also be empowered to formulate additional requirements which would put some of them on a much higher standard than they occupy at present.

3. Commitments are chiefly to be looked upon as reinforcements by the judge of the persuasions exerted by the friends, physician, and family of the patient, and should be resorted to only when the latter cannot be persuaded to go to the asylum.

4. Everything should be done to make the appeals of committed patients available. There should be severe punishment for the suppression of letters, or interference in any way with the alleged lunatic's rights.

5. There should be material reform in the attitude of the law regarding capacity and criminal responsibility, insane acts in themselves, in any relation they may have, receiving more weight than heretofore.

6. There should be a departure from conventions in old and arbitrary definitions.

7. Special insane acts should be studied with reference to the crime itself in a way they have not been up to this time.

8. The attitude of the courts should be much more charitable to the medical witness than it is to-day, the intelligent medical man being put in possession of all the facts in the case and not being obliged to answer restricted questions which place him in a false position, and which are deficient in the presentation of the facts.

9. In all matters involving the determination of capacity or responsibility the medical man should be required to prepare a brief which should form the basis of his cross-examination, and this, if necessary, must be supported by extraneous evidence which has received the sanction of the court as to heredity, previous history, and facts communicated by others.

OPERATIVE AND NON-OPERATIVE FIBROID TUMORS OF THE UTERUS.*

By FRANK DE WITT REESE, M.D.,

CORTLAND, N. Y.,

SURGEON IN THE CORTLAND HOSPITAL, VICE-PRESIDENT SIXTH DISTRICT BRANCH, MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Because of the great frequency of fibroid tumors in women I am led to discuss this question with you to-day. The number of women who suffer from fibroid tumors of the uterus far exceeds the number of those who are afflicted with other varieties of tumors.

While it is said that cancer is on the increase, and has been for a long time, it must be conceded that fibromyoma of the uterus, pure and simple, is still the tumor that is discovered the most often by the general practitioner, in city and country.

The question of operation for the removal of these tumors is of momentous importance to the patient, for she may be a girl of sixteen or a woman of fifty. To mutilate the generative organs of a young woman, who has a small fibroid of the uterus, unsexing her, or at least causing her to be sterile, when possibly she could be blessed by motherhood without it, I say such mutilation is as

*Read at Binghamton, N. Y., at the annual meeting of the Sixth District Branch of the Medical Society of the State of New York, October 6, 1908.

reprehensible as any damage that could befall a woman. Many women are known to carry fibroid tumors of the uterus from puberty to senile womanhood, without prominent symptoms. To say, as some writers do, that all fibromyomata should be removed as soon as diagnosed, is as unscientific as the statement is reckless.

When to operate, or not to operate, must be decided after a painstaking, discriminating diagnosis. Only after one has most conscientiously taken into consideration whether the tumor is simply a fibroid without complications, or whether it has complications or is a mixed tumor, can he decide to operate or not to operate.

I am persuaded that the greatest fault with the major portion of the profession is in overlooking early diagnostic symptoms and signs of uterine tumors, thus neglecting to make, or delaying in making an examination to ascertain the nature of the growth, until it becomes a formidable affair.

Last year at Ithaca, before this branch of the New York State Society, I read a paper on "Fibroid Tumors of the Uterus and Their Treatment," emphasizing the importance of recognizing dysmenorrhea at puberty, as an unfailing indication for an examination of the patient to ascertain and remove the cause of the dysmenorrhea. In that paper I stated that, of the last fifty cases of uterine fibroids seen in my private practice, forty-nine gave a distinct history of dysmenorrhea at puberty. Since that time I can add twenty-two more cases of uterine tumors to my series, and all but two of these gave a distinct history of pain with menstruation at puberty.

Of the seventy-one cases then, there were 95.78 per cent. that suffered pain and only 4.22 per cent. that did not suffer pain at the first menstrual period. What do these cases or statistics teach? Have we not the right to infer from them that, when a girl or woman presents herself to the physician with the history of painful menstruation, there is an abnormal condition of the uterus or endometrium that demands immediate attention, and the condition cannot be interpreted without a thorough examination of the pelvic organs? These statistics lead me to believe that many a woman could be saved the horrors of a uterine tumor, if the cause or causes of dysmenorrhea were removed early.

What physician has not had a patient say to him, while taking her history, that when she was a girl she used to have pain with her monthly sickness, but after her first labor the pain ceased; and then find upon examination a tumor, perhaps no larger than a pea or walnut, or one of considerable proportions? This must be the experience of many a careful observer. What does it all mean? It means, that to neglect the one symptom that is nearly pathognomonic of uterine tumors, is to neglect your patient at the time when prophylactic measures could be instituted.

The statistics associating dysmenorrhea at puberty, or at any other time, with uterine tumors, have been neglected. Such statistics are meager and incomplete. Dr. Cullen, of Baltimore, in a letter writes: "I have no statistics on this subject." Other writers have given nearly the same answer.

However this may be, I hope that the profession will carefully investigate the subject, and as they take the histories of their patients they will definitely ask this question: "With your first menstruation did you have pain?" I am persuaded that dysmenorrhea is an important diagnostic symptom of an abnormal condition of the generative organs, which favors the growth of tumors. The cause of the pain at menstruation, whatever it may be, should be removed at once. I have studied eighty-two histories of adenomyoma as given in Cullen's book on "Adenomyoma of the Uterus." Of these cases in thirteen menstruation was painless, 15.85 per cent.; in fifteen menstruation early in life was painful, 18.29 per cent.; in twenty-one menstruation late in menstrual life was painful, 25.6 per cent.; in thirty-three menstruation was not referred to at all, 40.24 per cent.

If you will carefully follow me you will see that there were thirty-six cases, or 43.9 per cent., in which painful menstruation was mentioned; there were also thirty-three cases, or 40.24 per cent., in which Dr. Cullen neglected even to mention the presence or absence of dysmenorrhea. If of these thirty-three cases there were 43.9 per cent., or fourteen, who, it is fair to suppose, did suffer from dysmenorrhea, this percentage added to the 43.9 per cent. would make 61 per cent., or fifty of the eighty-two cases, who suffered at some time from dysmenorrhea, and 39 per cent., or thirty-two cases, in which menstruation was painless. From the study of this series of cases we can further conclude that if Dr. Cullen had faithfully questioned these patients in regard to dysmenorrhea, he would have greatly increased the percentage of cases in which he would have recorded dysmenorrhea as being associated with uterine tumors.

Taking into consideration Cullen's imperfect records of uterine adenomyomata with the associated dysmenorrhea and those of my own experience (whole number of cases 153, of which 118 had dysmenorrhea), I am led to infer and conclude that, as dysmenorrhea is a symptom of uterine disturbances, it is the duty of a physician to ask for an examination *without delay*, because it portends for that patient, in the future, an operation for uterine tumor.

When will the general practitioner cease to treat dysmenorrhea with morphine, acetanelid, viburnum, whiskey, hot water bottles and many other things too numerous to mention, before he makes a discriminating diagnosis? We must never forget that dysmenorrhea is a symptom and not a disease of itself.

Dysmenorrhea is associated with uterine deformities, and with all pelvic tumors, cancers, adenomyomata, fibromata of the uterus, etc., ovarian tumors, and tumors of the Fallopian tubes. Therefore it behooves a physician not to play at treating dysmenorrhea, but to do business, and if the physician has not the training, courage or ability to do the right thing for his patients he should turn them over to a more competent physician. I never could see why it is not stealing to take a fee from a patient to whom one has not tried, to the limit, to give an equivalent for the patient's dollar, just the same as if one should filch a dollar from a grocer's till.

Whether a certain uterine fibroid should be operated upon or not depends, as I have said, upon a careful diagnosis, just the same as the treatment of any disease is undertaken after a thorough knowledge of the trouble is acquired. It is my opinion that a simple, uncomplicated fibroid never needs to be removed with the knife, but is always amenable to treatment. My conclusion is based upon the fact that the cause of the fibroid is some irritant, histological, mechanical, or chemical. Simple myomata seldom give rise to any symptoms, except dysmenorrhea, a slight change in the odor of the vaginal discharge, and pressure symptoms. Usually, however, the woman becomes nervous. This cannot be attributed, by her, to any defi-

nite cause, and is only accounted for when the interstitial fibroid is found, by examination.

To illustrate: Miss H., age thirty-seven, teacher, family history negative, always well, but somewhat nervous; tongue coated white, appetite good, constipated, urine normal. Had pain at first menstruation, but appears every twenty-eight days; pressure symptoms present, of late odor of vaginal discharge intensified. Examination revealed a uterus enlarged, due to a diffuse, interstitial tendency. One year later the fibroid was distinctly discernible. The diagnosis of fibromyomata of the uterus is attended by some difficulty because of complications, including hemorrhage, which hemorrhage might be due to an adenocarcinoma. A carcinomatous uterus is soft to bimanual examination, a fibroid is hard. Where adenocarcinoma is suspected, a curettage should be resorted to, and some of the scrapings should be examined microscopically. This should also be done in cases of suspected sarcoma. The indication for the removal of such tumors, carcinoma or sarcoma, of course, depends upon the microscopical findings.

The scrapings of the mucosa in simple fibroids and fibroids accompanied by hemorrhage, are those of the normal mucosa, or of atrophy due to pressure. Tumors of the uterus that were nearly always diagnosed as fibromyomata, until Dr. Cullen read his paper on this subject, are really adenomyomata. The distinguishing features in making a diagnosis in this are that the menstrual period in adenomyomata is lengthened, and there is a grinding pain in the uterus and possibly in the back and legs, while in fibroids the hemorrhage may come on in the interim. This is an important point to remember, for all the adenomyomata should be removed with the knife, and only a very small percentage of the fibroids should ever be touched with the surgeon's scalpel.

The operative fibroids of the uterus are: (1) Those associated with carcinoma and sarcoma; (2) all those tumors that are mixed with adenoma; (3) some of those tumors that give alarming hemorrhages; (4) those that are so large that they interfere with respiration and the function of the alimentary canal. These enormous fibroids are now seldom seen, because the surgeon has put in his work before they are allowed to attain large proportions; (5) the submucous variety; (6) the tumor that does not respond to local and systemic treatment after a good, fair trial.

The causes of fibromyomata are known only theoretically. There has been no cause advanced that satisfactorily explains the occurrence of this morbid growth. An unequal division of the chromosomes and cell protoplasm, as mentioned by Müller, is somewhat of a plausible theory, but I am led to believe that there is a cause that exists before unequal cell division is or can be noticed, and that is irritation, which is announced by dysmenorrhea at puberty. My clinical cases assure me that the primary cause is an irritant acting with a congenital condition, which results in overstimulation of the uterine cells.

My reason for thinking in this way comes from the results of treatment, constitutional and local. Out of 71 cases in my own practice, I can report a cure of 47. The rest of the cases remain as follows: One I advised to have an operation, and patient refused; four were operated upon, one by myself doing a vaginal hysterectomy, and the patient lived, the others were operated upon out of town, with two deaths; there are now eleven undergoing treatment, some of them are greatly improved, and about ready to be discharged; the other eight cases have drifted away, but were much improved before I lost sight of them.

I am well aware that many of the best surgeons in the country hold that immediate operation should be performed on uterine fibroids, and advise it because, first, there is but a small death rate from the operation; second, because of the tendency of fibroids to become malignant.

In answer to their first reason, "but a small death rate," I would say, death is not a pleasant thing to contemplate, and just so long as there is an admitted death rate from operations for the removal of uterine fibroids, I contend that the diagnosis should be clear and that the duty of every surgeon should be to withhold his hand until indications are unmistakably those that will warrant the operation, in view of this possibility of shortening a human life. I believe in bold surgical conservatism, based upon accurate knowledge of the conditions present, and actuated, not by commercialism, but by the spirit "as you would have them do unto you." It is folly to think that all uterine myomata even have a tendency to malignancy: it cannot be the fact. The fact is that it is the unrecognized mixed tumor that has a tendency to malignant degeneration, and that these tumors should be removed, there is no doubt, but the simple fibroid should not, because it is not malignant and causes but few symptoms.

I wish to give you the history and treatment of two cases of fibroid tumors of the uterus, from my own practice, because one is typical of the mixed variety, with malignancy; the other is the history of a fibroid, pure and simple.

Case I.—Mrs. H. consulted me July 8, 1908. American; age 41; married; occupation housework; also worked in the shop. Father died of bladder trouble and mother of a tumor in the right groin. Gave birth nine years ago to a full term child, and eight years since to a seven-months fetus. Following this labor she was very ill. Menstruation appeared at 14 years of age accompanied with pain. Menstruation, with pain, was regular until the birth of the first child; after that pain ceased. Had now been flowing for three months, sometimes more and sometimes less freely. Examination revealed a sloughing cervix, also small fibrous nodules in the body of the uterus. The diagnosis was a malignant condition of the cervix, associated with a fibroid condition of the uterus. I advised operation, to which she consented. Vaginal hysterectomy was performed by me July 13. The patient made a quick recovery, leaving the hospital in two weeks. The macroscopical appearance of the specimen confirmed the diagnosis, and the results justified the operation.

Case II.—Miss N. consulted me April 19, 1906. Age 27; servant girl; family history negative. Had symptoms of indigestion; constipated. With first menstruation pain, but the menses are regular in their appearance. Dragging feeling over right hip. Very nervous. Examination revealed an elongated uterus with a small fibroid of the fundus. Treatment was local and constitutional. Recovery was complete in two years.

The results in this case, as in the forty-six others that have recovered in my hands, appeal to my best judgment as a surgeon, in determining operative and non-operative cases. In the morning of life where there is a fibroid, withhold the hand until there is not a vestige of doubt left in regard to the advisability of an operation. In the evening of life, when degeneration of cell tissues is the rule, we need not be so particular in trying to save the gen-

erative organs, because at this time the organs have ceased functioning and to withhold the hand might be to miss giving the sought for blessing to the patient as her sun is setting. She should be operated upon, for she has reached the spot where she should rest.

Conclusions.—1. Dysmenorrhea should be considered a symptom when appearing in any period of a patient's life, justifying a thorough examination of the pelvic organs to ascertain the cause of the pain and its removal if possible.

2. A clear diagnosis and some positive indication for removal of uterine fibroid should be ascertained before surgical interference is resorted to.

3. Mixed tumors of the uterus should always be removed as soon as diagnosed.

4. Simple fibroid tumors should never be attacked surgically, unless in exceptional cases, because they are amenable to constitutional and local treatment.

BITUMINOUS COAL SMOKE: ITS CHEMISTRY AND EFFECTS ON THE HEALTH OF MAN AND PLANTS, WORKS OF ART AND COMMERCE.

By JOHN W. WAINWRIGHT, M.D.,

NEW YORK.

In an endeavor to determine the effects of coal smoke on the health of the community as well as of the individual, it will first become necessary to devote a part of this study to the chemistry of coal combustion, particularly bituminous coal, and the resultant products.

For our purposes we may consider smoke as the sign of incomplete combustion of fuel. During this process, small particles of unconsumed matter are blown into the atmosphere by gases liberated by the heat. In order to secure complete combustion, it is necessary that a high temperature be constantly maintained in order that all constituent gases be raised to the point of chemical decomposition. Bituminous coal contains, in addition to fixed carbon, a compound of carbon and hydrogen. These hydrocarbons are first volatilized by heat, setting free the hydrogen, which then unites with oxygen to form vaporized water or steam, while the carbon is set free. These particles of carbon rendered incandescent by heat, produce the flame. If at this point a sufficient supply of oxygen and the proper degree of heat are in evidence, the carbon will unite with oxygen to form carbon dioxide and the combustion will thus be complete. If, however, an insufficient amount of oxygen is supplied, free particles of carbon will escape, and this is smoke. Smoke is also produced through volatilization of the hydrocarbons, if the heat be less in degree than is necessary to free the hydrogen from the carbon, or if the heat be so intense that the fixed carbon is carried away before it has had time for combustion. This is the commonly accepted theory of smoke production.

In feeding a bituminous coal fire, decomposition will vary with the temperature, parts of the fire distilling off tar vapors rich in the paraffin hydrocarbons and yielding but feebly of gas; decomposition while under the influence of heat, if in contact with air and resultant gases at the surface of the fire bed, is affected by the composition of the coal, amount of air present, temperature, and the action of the products of combustion at the lower part of the grate, all of which make the process a complex one.

Flame is therefore caused by the combustion of gaseous matter. When the oxygen is supplied externally to the combustible gas, a hollow flame results, consisting of two parts, the outer where combustion is taking place, and the interior, which is cut off from a supply of oxygen, and not undergoing combustion, where active chemical changes are taking place under the influence of the burning envelope. Surrounding it, hydrocarbon gases and vapors are broken down and the simple hydrocarbon acetylene is produced. In the outer flame, or envelope, carbon and hydrogen compounds are being consumed with the formation of carbon dioxide, carbon monoxide, and water vapor. The dark inner zone, which may be regarded as a laboratory and gas store of the flame, is surmounted by a brilliantly luminous portion, which gives the major part of the cheerful firelight, while above this smoke begins to appear. These gradations are due to the formation of acetylene in the nonluminous core of the flame entering the heated zone of combustion, where the acetylene suddenly splits up into carbon and hydrocarbon; the latter burns and adds to the heat of the flame, while the carbon, raised to incandescence, partly by heat generated during its formation from acetylene, partly by heat from the flame and by its ultimate combustion, gives out the light. If sufficient oxygen is supplied to complete the chemical action, no smoke will escape from the flame and a far higher power of radiating light and heat will be produced. One finds, however, in practice that the diluting influence of the nitrogen and other products from the fire beneath and the cooling influence of the chimney draft which comes in contact with the flame, so check and otherwise influence the completion of combustion of the products from the decomposition of the acetylene that the top of the flame is cooled to a dull red and the flame extinguished before the carbon particles are consumed, this leading to the formation of sooty smoke, which passes up and out of the chimney.

A portion of the smoke consists of undecomposed tarry vapors, and a steam which is abundantly condensed from the watery vapor produced as one of the primary products of combustion. The tar vapor which escapes consists of a mass of vesicles, the outer surface or skins of which are formed of condensed vapor and liquid from the burning substance. They are filled with gases, are excessively light, and float in the atmosphere until brought into contact with some surface which causes them to burst and deposit the liquid film, setting the contents free. When the temperature at the top of the fire has been sufficient to ignite the gas escaping from it, these vesicles are not formed, and under such conditions only a small portion of escaping smoke is of this character. When the fuel has been placed on the fire in sufficient quantity to cool the top of the fire below the ignition point of the gas, the smoke which escapes consists chiefly of steam and this tar cloud. All smoke contains dust and ash from the grate.

It will be seen that there are four sets of particles formed in smoke: (1) Carbon particles which escape unconsumed from the burning hydrocarbons giving off the soot; (2) tar vapors; (3) steam; (4) small particles of dust mechanically carried up the chimney by the draft. The proportion in which the four occur in the smoke is entirely dependent upon the condition of the surface of the fire. When the fuel is first put on, tar vapor and steam only escape from the fire below, with particles of complete and incomplete combustion, among which are carbon monoxide. As the heat works upwards through the recently added fuel, the products of

distillation from the coal catch fire and are partially burned, the result being that the deposited carbon or soot also forms a portion of the smoke, while as the fire burns clearer and clearer and the upper portion becomes incandescent, practically nothing but the products of complete combustion find their way up the chimney. The gases issuing from a chimney consist, firstly, of invisible particles made up for the most part of gases which exist in the atmosphere in such minute quantities as to be capable of doing but little harm. This is true only of gases from ordinary fires and does not refer to the fumes from the chimneys of chemical works, which are capable of doing great harm. Besides these invisible gases, as we have shown above, there is the visible portion, consisting for the most part of minute particles of carbon, which are not entirely pure, but contain a certain amount of sticky, tarry matter.

The smoke, after issuing from the chimney, becomes dispersed in the air to a height of some hundreds of feet above the ground. This widely distributed smoke gradually settles, clinging to anything that presents itself. The ground, the walls and roofs of buildings, the trunks, branches, and leaves of trees and shrubs, the exposed parts of the person and the clothing, all come in for a share of the all-enveloping cloud. Where the surfaces are smooth and exposed to the washing action of the rain, as in the case of roofs of buildings, very little of the dry carbon itself remains, but only the more sticky substances, which cannot be easily washed off. Rougher surfaces, such as stone walls, and especially trees and shrubs, retain the black dirt far more readily, and become permanently coated with a sticky, sooty film.

From an esthetic point of view the effect of smoke is as bad as it can be. In our large manufacturing towns, where the atmosphere is very heavily laden with soot, all the stone buildings become in a very short time nearly black, the stone presenting a more retentive surface than the smoother brick, though brick buildings do eventually become coated in much the same way. Those who are familiar with such cities as Buffalo, Pittsburg, Cincinnati, Cleveland, St. Louis, Chicago, and places of smaller size and lesser note in our middle and western States, where bituminous coal is almost entirely used for manufacturing and heating purposes, cannot fail to appreciate the terribly disfiguring effects of exposure for a few years to this atmosphere, heavily laden with black smoke. One feels that this disfigurement of public and private buildings, though only one of the lesser evils of black smoke, is sufficient reason for the most vigorous crusade against those who, by their negligence or obstinacy, contribute to the pollution of our atmosphere.

The disfigurement of buildings is, perhaps, less objectionable than the coating of black which settles on all the vegetation in a district pervaded by smoke, for, besides the dullness imparted to the colors of the plants and trees by the layer of soot, the blackness of the trunks and branches of the trees, and the unpleasantness in touching or allowing portions of one's clothing to touch them, there can be little doubt that the vigorous growth of a plant is to a large extent interfered with by the presence of a film of an oily substance on the surface of the leaves. At the same time, much of the unhealthiness of plants attributed to smoke is very likely due, not so much to this as to the presence in the atmosphere of deleterious acids, more particularly sulphurous and sulphuric,* which are formed along with the smoke. The breathing pores of a plant are on the under side of the leaves, and while it is on the upper surface that the greatest deposit of soot takes place, some small quantity also clings to the under side.

The atmosphere is what we breathe, and upon it we depend for our very existence, and it is therefore necessary that we should be as careful that we breathe pure air as we are that the water which we drink is without contamination. Life in a smoky and crowded town is not, and cannot be, so healthy as a life which is spent in a pure atmosphere, free from the contaminating effects of smoke and its accompanying products. It is well known that the urban population is tending to deteriorate and is only kept up to a reasonable standard by the continuous influx of workers from the country districts, the tendency being for people to crowd to the towns for work and higher wages. The town population is increasing rapidly year by year, and there is a corresponding decrease continually taking place in the number of inhabitants in the country districts. Though in many directions the conditions of town living are being improved—greater attention is being paid to sanitation, the dwellings of the working class are on the whole improving, and the public authorities are waking up to the necessity for plenty of open space—still the two facts remain, that the population in the smoky areas is very much on the increase, and that the atmosphere in these areas does not improve.

Without doubt, the existence of a smoky atmosphere has an influence in increasing mortality. This is a statement well worth consideration, and should claim the immediate attention of our public health officials. One effect of a smoky atmosphere, even worse than that of breathing the vitiated air, is to be found in the indirect effect, in causing people to keep their windows shut in towns, and so breathe the even more vitiated atmosphere within. It has for some time been recognized that one of the conditions most favorable to consumption is to be found in defective ventilation.

Another effect of a smoky atmosphere, and one often lost sight of, is the effect that the presence of soot in the air has in shutting off and obscuring the sunlight, which is so important to healthy life. This may easily be noticed on going into a large town by train from a clear country atmosphere. As the town is approached, the sunlight gets less intense, and often in the winter months it is found to be nearly dark when the center of the town is reached. This is always so to some extent, the only variation being one of degree. Here we find the same injurious effect upon vision as is encountered in a dimly lighted room, where the occupants are subjected to a continuous eyestrain, the result of which is headaches and a whole train of disorders to health.

Under certain meteorological conditions this pall of smoke becomes a veritable blanket, filtering its way into homes and public buildings.

There is little doubt that the presence of smoke in the atmosphere assists very largely in the formations of fogs. The smoke in the air becomes generally diffused, so that the whole volume of the atmosphere gets to consist of pure air throughout which are numberless small particles of carbon, each one of which may serve as the nucleus of a foggy globule. In certain states of the atmosphere, such

*Dr. Charles Baskerville has calculated that in New York City 1,300 tons of 80 per cent. sulphuric acid are set free daily from the combustion of ordinary fuel.

as dryness, pressure, low temperature, and stillness, the aqueous vapor becomes partially condensed, it being generally supposed that each carbon or dust particle acts as a nucleus around which collects a small globule of moisture, the summation of these making up the yellow fog with which our largest towns are so strongly oppressed during the winter. A reduction of the number of smoky particles in the air might be expected to reduce the density and dirtiness of our fogs, if not to do away with them altogether. Fogs are not confined to towns, but the fog of the country is a white innocuous mist, which may be unpleasant in some ways, but never assumes the density of the real town fog, nor does it soil the linen, make the eyes smart, or clog the lungs of all persons exposed to its effects.

It is stated that there are about fifty tons of soot and two hundred and fifty tons of carbon dioxide in the atmosphere immediately above London, and this in spite of the fact that the means taken for the prevention of the emission of black smoke are much more definite, and the laws relating to smoke are much more stringently enforced, than in cities and towns in this country. No doubt the smaller industrial and domestic fires are to some degree responsible for the smokiness which is found in the smaller centers, and although people are found who insist that a smoke evil due to house fires is to some extent in evidence, the fact remains that in such places the atmosphere is without doubt purer in every way; buildings are cleaner, trees and plants flourish, and the appearance of everything is brighter than where there are a number of factory chimneys pouring out smoke and sulphurous gases.

Some interesting and valuable results were obtained a few years ago by Dr. Cohen, of the Yorkshire College, Leeds, in connection with the quantity of smoke to be found in Leeds, one of the smokiest cities in England. These results were published in 1896. He found that in every 100 cubic feet of Leeds air there were about 12 milligrams of soot. This he did both by estimation from the amount of coal burnt per day in Leeds, and also by the more direct method of collecting known volumes of the air, separating the soot, and weighing it. He estimated the amount of coal burnt per day in Leeds as 4,000 tons, and that of this one-half per cent. escaped into the atmosphere as soot. This gives about twenty tons of solid smoke sent into the atmosphere, and of this Dr. Cohen found by weighing the soot collected from melted snow, that half a ton falls on the immediate area, and that of this twenty to twenty-five pounds is not removable by rain.

A prominent merchant doing business in Chicago asserted recently that in his establishment alone the value of goods was reduced $200,000 last year because of being soiled, most of which soiling was due to smoke in the atmosphere; and he believed the total loss to all merchants on State street, that city, during the year must have approximated $2,000,000. "In fact," said he, "I believe the damage caused in our city by this black smoke amounts to more every year than the total taxes paid by the city, and when you consider that there is over $40,000,000 annually paid in taxes, it makes it a subject worthy of consideration."

We constantly hear it stated that visible smoke is the cause of high death rates, and that it has a serious influence upon the health of the community. It must be admitted that the products of combustion do interfere materially with the welfare of a community (1) by conducing to the formation of fog and rain; (2) by shutting out sunlight and depriving us of certain qualities of light, of great importance in regard to changes in organic matter; (3) by depositing soot and rendering houses and their contents dirty. There is no doubt that the presence of smoke in any quantity in the atmosphere has a prejudicial effect upon us by depriving us of sunlight, and this is a sufficient reason in itself for stimulating every one to effect, as far as possible and by every means in his power, a diminution of the nuisance. Apart altogether from fog, smoke hanging over a town forms a barrier to the sun's rays; and although the heat rays may pass through readily, the blue rays, which are of the greatest importance to healthy vitality, are kept back. This opacity of smoke to light is one of its most objectionable characteristics, as neither animals nor plants can thrive when deprived of light. In the poorer districts of every large town the inhabitants, deprived of light to a large extent, show a lower vitality and capability of resisting attacks of disease. Within the last few years another important action of light in this respect has been demonstrated: the powerful destructive influence sunlight has upon various forms of bacteria and disease germs, and in the case of one form in particular, the tubercle, bacillus, it has been shown that this organism succumbs after a short exposure to light. Organic changes, or oxidations, which are impossible in darkness readily take place in sunlight, and this fact also is of great importance in the economy of human life. The third undesirable effect of smoke is the dirt which results from the deposit of the unconsumed particles of carbon as soot. Among the poor, especially, cleanliness of surroundings is an important factor in influencing their lives, both morally and socially, and it must be admitted that the smoke nuisance, where it exists to any large degree, has an important bearing upon the welfare and social condition of this class of a community.

It has been asserted that in suppressing smoke we deprive ourselves of a powerful disinfectant, which, when in the atmosphere that we breathe in crowded cities, tends to guard us against contracting infectious diseases, especially of the nose, throat, eyes, and lungs. This theory is, of course, discredited, for, as a matter of fact, such infectious diseases are more prevalent in large manufacturing centers than elsewhere, and statistics show this to be in a large measure due to a coal-smoke ladened atmosphere. A smoky atmosphere, by its exclusion of light, its content of acid and irritating particles suspended in it, is harmful to the tissues of the nose, throat, eyes, and especially the lungs and air passages, whether in a healthy or other condition; aggravates the discomfort of those suffering from all forms of heart disease; increases the distress of those who have nervous complaints; lowers the tone of general health; is a peril to the aged; diminishes buoyancy of spirit, as well as reducing still further an already lowered resistance to disease.

What relative part with pathogenic germs smoke plays in causing this class of diseases it is hard to calculate, but it is safe to say that, working together, the danger to health and life is largely increased. In Manchester, England, the death rate from diseases of the respiratory organs was, in 1874, 7.7, in 1893 23.2 per 1,000 of all deaths, while in Westmoreland, England, the death rate was from the same disease but 2.29 in 1888 and 13.7 in 1893. These increased death rates are charged to an increased consumption of coal and consequent production of smoke. In Prussia there were 96,235 deaths from acute pulmonary affections in 1903. In addition to these there were in the same year and country 70,049 deaths from tuberculosis. How many of these resulted from breathing coal smoke is not stated, but it is a notorious fact that almost the whole of Prussia is covered with smoke coming from innumerable factories in constant operation.

CHRONIC OTITIS MEDIA PURULENTA.

By ALFRED WIENER, M.D.,

NEW YORK.

Although the views expressed in this brief paper may not add anything materially new in regard to this very important subject, nevertheless it seems to me that if a greater number of otologists who are experimenting with the measures advocated here for the treatment of chronic suppuration of the middle ear would relate their experiences, we could eventually come to some conclusions. We should emphasize more strongly than heretofore such measures as we have found practical and of real benefit to the patient. One need only to scan the literature upon this subject and one will find sufficient evidence to persuade us to be more conservative. There have been several contributing causes which have brought about such a persuasion. Briefly stated, we might mention the following:

(1) A patient with a chronic otitis media purulenta, from which he has suffered for a period of ten years or more, and for which he has undergone treatment in a haphazard way, submits to the ordeal of a radical operation. The operation reveals a solid mastoid, and not until the antrum and tympanic cavity are reached do we find any evidence of disease. Such patient is submitted by the physician to all the risks which are attendant upon this operation. The findings prove that the surgeon might have succeeded just as well by adopting conservative measures in a manner such as I will explain further on in this paper.

(2) Time and time again serious damage is done to parts because the familiar anatomical landmarks cannot be recognized, and a permanent injury to the patient is the result of a radical operation.

(3) We have learned to recognize the fact that when conservative measures are employed under the supervision of an otologist and are unsuccessful, no real harm is done to the patient.

(4) Furthermore, such preliminary measures will in the end assist in many ways to simplify the radical interference.

If we glance for a moment at the pathological condition present in these cases, we find that there exist all the stages of a chronic inflammation of the mucous membrane, and the results attendant upon such an inflammation. We find a thickening of the mucous membrane, exuberant granulations, and polypoid formation, with profuse discharge. Adhesions form which shut off portions of the tympanic cavity. Retention and decomposition of the secretion takes place with a resulting caries and necrosis of bone. In other cases there is the formation of cholesteatoma with its resulting destructive tendency. Finally it is well to remember that the above conditions may be present and due, not to some local cause, but to a tuberculous or syphilitic diathesis.

What I wish especially to emphasize in this short paper, is the plan of treatment to which I think most patients are willing to submit, and which will give them the most satisfaction with the least amount of risk. When we meet with patients suffering from a chronic discharge from the ear we should first of all impress them with the fact that such a condition, if allowed to continue indefinitely, is a matter of serious concern. Every means should be employed to cause a cessation of this discharge—first by conservative local or operative measures through the external auditory meatus, and then, if not successful, they must submit to more radical measures.

Before attempting any conservative measures it is quite natural to suppose that we have convinced ourselves that, with the exception of the usual symptoms accompanying such chronic discharge, there are present no symptoms of a serious nature. None should exist that point toward the invasion of vital parts. In such cases delay in radical interference would be at great risk to the patient. It is not necessary for me to mention these symptoms as they are well known and easily recognized and their significance understood. The existence of a chronic discharge for ten years or more need not deter us from pursuing conservative measures. I have seen such cases under proper treatment improve within ten days and in from two to three weeks apparently cured.

In treating these cases we should try to determine what is at fault and what is keeping up this chronic discharge. With the exception of those cases in which a tuberculous, syphylitic, or other dyscrasia is present, I think we will find that proper drainage is wanting. Furthermore, even in such cases in which a tuberculous or syphilitic diathesis exists, when proper drainage is established and the necessary constitutional treatment prescribed, it is surprising to see how even these cases will respond.

It is our duty, therefore, to employ such measures as will establish proper drainage. We should then teach these patients how to keep their ears clean. By means of local measures assist such cleansing processes from time to time to bring about a healthy condition of the diseased area. Soon our pains will be rewarded and our patients gratified to find that the discharge is lessening and that the inflammatory process has become quiescent.

To bring about this drainage, first of all the entrance to the tympanic cavity must be sufficiently free of all obstructions to permit one to wash out with the tympanic catheter and treat locally the walls and accessory cavities. If there is only a small perforation, such perforation is enlarged. If there are exuberant granulations or polypoid formations present they are removed. If adhesions exist they are divided. If they recur and it is found that they cannot be prevented without sacrificing the malleus and incus, an ossiculectomy is performed. This usually proves successful. One need not hesitate about removing both the malleus and the incus, as in the majority of these cases they have already lost their usefulness, bound down as they are by adhesions, often carious and only exerting a baneful influence by their presence. When the hammer or incus are found carious, in order to observe and treat locally the epitympanic space, as well as to reach the antrum, which will usually be found diseased, a modified Stacke operation is performed through the external auditory meatus. All these measures I have succeeded in accomplishing by means of local anesthesia, as practiced by Neuman of Vienna.

In those cases in which there is an evidence of cholesteatoma with chronic discharge, it is best to advise at once radical measures and not attempt any conservative treatment.

With such operative measures as recorded above, followed by local treatment at stated intervals, as the case may demand, at home the use of some mild antiseptic wash and astringent, preferably alcohol in varying strengths, it will be surprising to see how some of the most stubborn cases will respond. At the same time the constitutional condition of the patient must be taken into account and treated. All nasal and nasopharyngeal disturbance must be corrected. Especial attention should be paid to the Eustachian tube which will often be found in a catarrhal state.

Patients who submit to such conservative measures must be led to understand that they must keep themselves under the observation of the physician in charge until the ear is quiescent. This is necessary, for should any symptoms arise that may occasion concern, radical measures can be instituted at once. Furthermore, they can also be instructed, that these measures which are conservative, at the same time may also be considered as preliminary, if a radical operation is deemed necessary later on. I would like to state right here that in those cases in which a radical operation is deemed necessary, and such preliminary operative treatment has been followed out, the radical operation is very much simplified.

In regard to the results obtained, my own experience has led me to believe, that with our improved methods of treatment the average number of cures is greater than heretofore. Some cases, of course, will not respond. Some will be very much benefited and serious complications reduced to a minimum. Some will remain quiescent for a time, become active again on account of some aggravated throat trouble, but respond again to treatment. Others will compel us after an extended course of treatment to resort to the radical operation, and a cure will be established. In others, in spite of the radical operation, the hoped for cure will not be brought about.

In regard to the conservation of hearing, a very important consideration when operative measures are about to be performed, my own experience has taught me that in those cases in which conservative measures are attempted and with success, a great deal more is to be expected and can be promised than when the radical operation is performed.

In regard to syphilitic and tuberculous cases the prognosis, so far as a cure is concerned, is about equally divided, between conservative and radical measures.

FRACTURE AND DISLOCATION OF THE NECK, AT THE SIXTH CERVICAL VERTEBRA, IN A MAN OF 60. RECOVERY.

By GEO. HERBERT WILLIAMS, M.D., M.R.C.S., Eng.; L.R.C.P., Edin.;

FISHKILL-ON-HUDSON, N. Y.

VISITING SURGEON TO HIGHLAND HOSPITAL, MATTEAWAN, N. Y.

About five o'clock on the morning of October 5, 1907, I had an urgent call to see P. K., who had fallen off his piazza the night before. On reaching the house a few minutes later I found the patient, a powerfully built man of a little over sixty years of age, and a grand army veteran, lying on his back in bed. The history of the fall he and his wife gave me was that about eleven-thirty the night before, on his return home with three heavy ledgers under his left arm, he was trying to unlock the front door, when the middle ledger slipped from between the other two, and as he made a sudden move to the left to break its fall, or check it, he lost his balance and toppled over a low railing at the side of the piazza and close to the front door, and that he struck the ground about six feet below, landing on the top of his head; his wife had heard him at the front door and as he did not appear soon she went to see what was the trouble. She heard groans at the side of the house, and found him lying on his side unable to move. Some of the neighbors were summoned and he was picked up and carried to his bed. His family did not, of course, appreciate the gravity of his condition, and thought him merely stunned, hence the delay in calling for medical assistance.

The patient was lying on his back with the chin drawn down, the position reminding me of a turtle with its head partially thrust out. There was complete paralysis below the line of the neck, both sensory and motor paralysis. He was unable to move hand or foot, or to feel pin pricking until the descending branches of the facial nerve were reached about the line of the clavicle. The pulse was slow and full, the respirations were very characteristic and were eight or nine to the minute and diaphragmatic entirely; the diaphragm was the only muscle of inspiration he was using or could use.

On passing the fingers along the region of the neck there was felt a fulness with an irregularity over the sixth cervical vertebra. The patient had not urinated since the night before so I passed a catheter and drew off about a pint of pale amber-colored urine. I assured the family that there was small chance of his living for many days and insisted on his removal to the hospital, to which they agreed. The patient was placed in the ambulance and carried to the Highland Hospital. I called my colleague, Dr. McClintock, in consultation, and, as the case seemed desperate, we decided on attempting reduction. Dr. McClintock made gentle extension and rotation of the head, standing at the top of the bed, grasping the patient under the occiput and lower jaw, while with the fingers of both hands at the back of the neck I made gentle but firm pressure over the side of the sixth cervical vertebra. After several attempts of this kind we were delighted and relieved to hear a decided snap, which both Dr. McClintock and I, as well as the patient, heard, and which the patient felt, as he immediately remarked "something went back that time, ah, now I feel!" He was at once able to draw his left arm up and on toward the middle line of the body. This was the first move he had made in about eight hours.

Having effected this reduction a back splint was applied fastened about the chest below and the forehead above, strengthened by small shaped splints at the side of the neck, and the head was securely fixed by sand bags. I saw the patient about an hour later and was pleased to find that he had regained entirely the movement as well as the sensation in the right arm and leg; motion and sensation did not return until two days later in the left leg. The patient had retention of urine, necessitating the use of the catheter night and morning, until the evening of October 11, when he had incontinence and dribbling of the same. At my afternoon visit the same day I found the patient had passed a fairly comfortable day, sleeping a good part of the time, his temperature was 100.3°, pulse 86, and respiration 22. The abdomen was very distended, and an enema was ordered which resulted in the escape of a small constipated stool and a large amount of flatus. The next morning I found the patient had rested fairly well and his condition was not much changed. That day at my afternoon visit the temperature had fallen to normal and the pulse was 80, respiration 20. At my morning visit on the 7th, the third day after the accident, the nurse reported a fairly comfortable night, later in the day the temperature rose to 101°, pulse 78, respiration 24, and I found still a great deal of distention of the bowels, and the stomach was intolerant of all nourishment. This condition was relieved by a high enema of Epsom salts and glycerin in hot water. Distention of the bowels was a prominent

and distressing symptom for the first few days of his sickness. On the morning of October 8, the temperature was 100.4°, pulse 76, respiration 21, and the patient had developed a short and troublesome cough. Fearing hypostatic pneumonia, I at once ordered his removal from the regular hospital bed and placed him on a Gorham bed, and I consider this to have been a most important part of his treatment, as it allowed of a change of position several times a day.

I will not go into the details taken from the hospital notes, which are often so tedious, but choose what seems of especial interest from them. The patient had in addition to the symptoms above enumerated, severe constipation and ammoniacal urine, such as we usually find in this class of case, also a tendency to bed sores, difficult to heal, and a persistent eruption on the lower part of the back and the left calf, which was eczematous in character and yielded ultimately to ten minim of Donovan's solution after meals. One important feature of the case was that the left arm, which was the first partially to recover motion after the reduction of the dislocation, some two days later began to lose motion, but not sensation, gradually and most markedly below the elbow, and in spite of massage and electricity, which was begun early and is still kept up, the muscles of the hand and forearm became atrophied until the hand presented the appearance of a case of progressive muscular atrophy, and the hand was drawn decidedly toward the ulnar side. On November 16, I found slight extension and flexion of the left thumb, and now, nearly a year later, the arm and fingers are stiff and the whole limb is of very limited use. The patient was kept in bed for twelve weeks, being allowed to sit up in a chair on December 28. On December 29, from the hospital notes, I find the flexors of the left arm are flabby and the muscles of the upper arm atrophied; there is slight extensor movement at the wrist, but the extensors are, as a whole, much atrophied, and the hand is drawn over to the ulnar side; the patient cannot bend the fingers or approximate the thumb.

On January 11, 1908, I find a note to the effect that he is gaining more control over the bladder; on this day also the patient was able to take four steps unaided. On January 26 the patient, who had been gradually gaining strength was allowed to return home. He now walks well and firmly and goes down town on fair days and moves about at his own pleasure. The muscles of the upper arm are improving in tone and power and he can now approximate the thumb to all his fingers except the little one, and so can help himself in many ways, by holding his paper and feeding himself. He can bend the elbow more each week and seems very cheerful over his condition; he is still obliged to wear a rubber urinal during the day, as he is never certain of himself in this particular, although the intervals between urinations are gradually lengthening.

I have gone over the case with Dr. Robert Abbe of New York and he has thought it of great interest and well worth reporting in view of the severity of the case originally, and the patient's age. We have assumed that the dislocation tore one or two root nerves on the right side at their exit from the fifth or sixth foramen, probably both, and therefore recovery has been proportionately slow and incomplete, and again pressure on the cord, mechanical and not from hemorrhage, must be regarded as the immediate cause of the paralysis below the neck, inasmuch as this symptom so quickly disappeared.

IMPORTANT FLAT-FOOT FACTS; FOR ASSIMILATION AND DISSEMINATION.

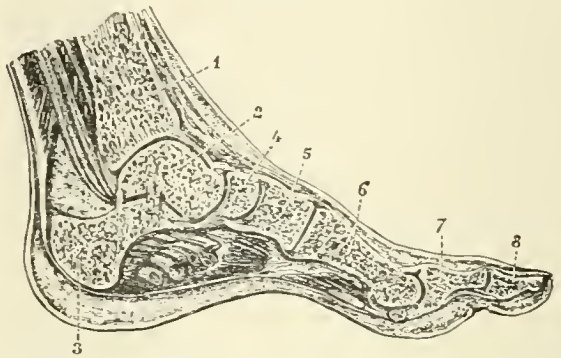
By EDWARD A. TRACY, M.D.,

BOSTON.

ORTHOPEDIC SURGEON TO MT. SINAI HOSPITAL AND TO THE BOSTON EMERGENCY AND GENERAL HOSPITAL, AND CONSULTING ORTHOPEDIST TO ST. MARY'S INFANT ASYLUM.

Flat-foot should be more generally recognized in its very incipiency. This recognition is not difficult, as I shall show further on. This incipient condition, going untreated, terminates in various degrees of flat-foot, and finally, the instep arch is so completely down, that no medical skill whatever is required to make the diagnosis—a glance at the foot suffices.

For better comprehension of our subject a brief consideration of the normal arch will be helpful.



Antero-Posterior Section of the Foot. 1, Tibia; 2, astragalus; 3, os calcis; 4, scaphoid; 5, int. cuneiform; 6, first metatarsal bone; 7 and 8, phalanges of great toe.

The illustration, taken from a frozen section, shows beautifully the normal instep arch. The keystone of the arch is clearly seen to be the scaphoid bone. With the scaphoid in its right place the arch is normal. The arch normally is held up by the leg muscles—especially by the front and back tibial muscles. In their normal condition of tonicity, there is no falling of the arch, and the arch functionates perfectly, enabling us to walk, run, and jump without pain, and, within limits, without tiring.

When, however, the leg muscles lose their tonicity from any cause, the arch commences to fall, and the signs and symptoms of falling arches are plain to him or her who looks for them.

We can see how important it is to know the causes of loss of muscular tone in the leg muscles, if we desire to diagnose falling of the arch at its very beginning. Muscular tone is the constant tendency in muscular tissue to contract. It is a property of muscular tissue, and has no relation with voluntary motion. It is in virtue of muscular tonicity that both surfaces of a cut muscle retract. This property is lost by overuse or fatigue.

We now see why occupations that are associated with excessive use of the leg muscles, thus causing their fatigue and consequent loss of muscular tonicity, are occupations in which flat-foot is very common. Policemen, motormen, conductors, and postmen are examples. The very nature of their occupation, which causes strain and fatigue of the leg muscles and consequent loss of muscular tonicity, is productive of flat-foot. As a rule, in them it goes unrecognized until painful locomotion brings them to the specialist with chronic flat-foot, which could easily have been prevented, as I shall show later on.

Occupations in women that I have found most

frequently associated with flat-foot of various degrees are those of salesgirl, nurse, servant, and housewife; and for the same reason, namely, overfatigue of the leg muscles with a consequent loss of their tonicity, thus permitting the arches to fall.

So much for occupations that have a tendency to produce flat-foot because of their fatiguing the muscles that normally hold up the arch.

There is another cause of loss of muscular tonicity in the leg muscles that accounts for almost all the cases of flat-foot met with outside these muscle-straining occupations, and that cause is sickness, sickness of any nature that confines one to the bed for a week or more. The simple lack of use of the leg muscles for such a period produces a condition of weakness in these muscles that allows them to become easily fatigued, and with fatigue of a muscle always follows the loss of its tone. More marked indeed is this muscular weakness in infectious diseases, aided probably by the toxins circulating in the blood in such cases. The weakness of muscles engendered in fever cases is always manifest when the patient leaves the bed—he can hardly stand. Then can be detected acute flat-foot, if we look for it. The scaphoid, the keystone of the arch, sinks, there is often pain in its neighborhood, and there is always a tired, aching feeling in the leg when the body weight is borne on it for some time.

In some cases the muscles regain their tonicity before becoming permanently stretched, and these cases—very few indeed—regain their normal arches. All cases of acute flat-foot would recover if the scaphoid was kept raised to its normal height until the leg muscles had regained their tonicity.

The better term for these incipient cases of flat-foot is falling arches. On inspection, these cases do not show the condition so readily recognized as flat-foot. On the contrary, if the arch be examined with the patient sitting and bearing no weight on the foot under inspection, a very beautiful and apparently normal arch is often seen. Let the patient, however, stand and bear weight on the arch, and it falls, sometimes being wholly obliterated, and a condition of flat-foot is very evident.

In cases in which the arch falls but slightly, one might be in doubt about the diagnosis. A therapeutic test is here decisive. Place properly constructed and fitting arch supports under the arches, and immediately the discomforts caused by incipient flat-foot (tired leg muscles and aching feet, especially as the day wears on), disappear, and the patient feels a sense of relief and comfort that indicates that our treatment has cleared up our diagnosis.

Incipient flat-foot, or falling arches, is a very common condition. It is not diagnosed as it ought to be, for the same reason that led Sam. Johnson to define the pastern as the knee of a horse—sheer ignorance. The wisest of us must needs be ignorant of many things, but let us hope not invincibly so. In this brief paper I have aimed to make plain that the chief factor in the etiology of flat-foot is muscular fatigue causing loss of muscle tone; that this is caused by occupations requiring much standing; that it especially follows after sickness necessitating a period of lying in bed (and here let me mention childbed particularly); that the resulting falling arches, or incipient flat-foot, is curable.

I could print many cases demonstrating these facts. They are so common in my experience, that for their confirmation I simply invite the careful observation of similar cases by my brother practitioners in their own practice. The cases they will find frequently enough if they will but look for them.

A word about the treatment of flat-foot will be added, for that, to the practitioner, is perhaps the most important part of the subject. In incipient flat-foot, if the scaphoid bone be supported in its normal position until the leg muscles regain their normal tonicity (generally a period of three to six months), a cure results, and flat-foot is absolutely prevented. The problem of a proper support for the scaphoid is not so simple as it appears, for there are many conditions to be considered relating to the anatomy and physiology of the foot, the construction of the shoe, and the degree of flat-foot present.

Rigid plate supports interfere with the physiological action of the arch, and are to be avoided. The support I use with constant success in the treatment of flat-foot of every degree is adjustable, is elastic, is light, and comfortable from its first application. The device consists of springs, in numbers one, two, or three, according to the degree of flat-foot and to the weight of the patient, inserted into leather, molded to conform to the normal arch. I have a capping over the springs that insures the correct conformation of the leather under the arch to the scaphoid and adjacent tissues. The scaphoid can thus be supported without undue pressure, and adjustment of the support for different degrees of flat-foot can be readily effected.

When all are alive to the necessity of properly treating falling arches, an affection that is far more common than is suspected, we shall see very few cases of flat-foot develop. There is no reason why it cannot in every case (except severe trauma) be prevented.

When flat-foot is developed it can be readily relieved by the arch support I have mentioned; but in flat-foot the old adage is eminently true—"An ounce of prevention is worth a pound of cure."

509 Broadway.

Flannelette.—The difference between ordinary cloth and flannelette is that the latter has a nap which is obtained by "raising" one or both surfaces by passing it over revolving rollers provided with steel dents or teeth which draw from the surface a nap which forms a better nonconducting material for heat than the original cloth and which, therefore, gives a greater feeling of warmth to the person using it than does the "unraised" fabric. The impression is that this raised surface is a source of danger from fire, that it presents a sort of cotton-wool surface which readily catches fire and burns with considerable energy. It is generally believed that it is advisable for children's clothing to be made of woolen or a mixture of woolen and cotton fabric or of flannelette which has been treated so as to render it noninflammable. There is nothing to be said against the proper employment of flannelette for its nonconducting properties coupled with its porous character make it a most useful material for cold weather. It has not the disagreeable cold feel of ordinary smooth garments, a fact which has been appreciated by rich and poor alike. To the latter in particular the invention has been a real boon as supplying a warm and cheap garment for winter wear. All these points in its favor do not alter the fact that it is an easily inflammable substance. Adults may be expected to wear this material without running risks of setting it on fire but with children the case is different. Children do not know of these risks, and we have no doubt that there are instances of their getting burnt even when clad in a nightdress of ordinary nonfluffy material. The risk is, however, dangerously intensified when the material is fluffy, as is the case with flannelette.—*The Lancet.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, November 7, 1908.

FUNCTIONAL EFFICIENCY OF THE HEART.

DEVIATIONS from proper function as contrasted with changes of form and structure have of late attracted more attention from clinicians, such study promising to throw more light upon the practical questions of medicine than the older methods of determining anatomical changes in the organs of the body. This change of view is especially prominent in the study of the heart; a few years ago gross anatomical changes determined by percussion and auscultation were alone considered in the treatment and prognosis of heart disease, with the result that many a victim promised but a short span of life because of an hypertrophy or a murmur discovered by his physician, continued for many years to be a living evidence of the inexactness of diagnostic methods. Several methods have recently been proposed for the determination of the functional condition of the heart, but the general practitioner who may not be in position to verify the results with the help of all the modern laboratory methods of research is often unable to decide which of them is most reliable and best adapted for everyday practice.

In a dissertation dealing with the subject (Functional Capacity of the Heart, St. Petersburg, 1908) S. E. Biron attempts to give the results of parallel experiments with several such methods of diagnosis. The value of knowing the functional condition of the heart is evident: after acute diseases such knowledge may prevent overstrain by injudicious exercise and may thus save the patient from sudden death or chronic invalidism; in valvular diseases it gives a clue to the condition of the heart muscle and therefore to the prognosis of the case in question; for the surgeon it may decide the advisability of omitting an operation or the choice of an anesthetic; prophylaxis of heart disease in persons predisposed to it because of an inherited or acquired weakness of heart muscle may be intelligently arranged; and, finally, the treatment of actual heart disease is made more exact and therefore more successful. The first method considered by Biron is that of Katzenstein, who noted that in healthy persons the blood pressure rose from 5 to 15 mm. when the femoral arteries were compressed, while the pulse was little affected at the same time. In insufficiency of the heart the blood pressure either remained stationary or fell, while the pulse became more frequent. Biron's numerous observations confirm in general the data given by Katzenstein, though he warns against attaching too much significance to the results obtained at any one observation; moreover, the method requires the use of more or less complicated blood pressure apparatus and cannot be carried out without the help of an assistant.

Gräupner has quite recently proposed to estimate the efficiency of the heart by the effect of muscular work upon the blood pressure curve; he observed that certain regular muscular efforts regulated by mechanical flexion and extension of the arm resulted in the fall of blood pressure after the motions were stopped, if the heart of the patient was not normally efficient; if the inefficiency was secondary to arterial conditions the blood pressure rapidly rose to normal figures and beyond them; if the heart was primarily at fault the return to normal pressure was slow and the rise over normal figures was not observed at all. Neither Klemperer nor Biron, however, could confirm the regularity of these results while noting that in individual instances the ability of the heart to perform any special work might perhaps be determined by the use of Gräupner's apparatus. There remained a third much older and simpler method of testing the efficiency of the heart, namely, the study of the lability of the pulse in changing from a vertical to a horizontal position. Biron was able to confirm the data of numerous observers in showing that the pulse of healthy individuals was slowed by from 5 to 25 beats in such change of position; in convalescents from acute disease as well as in those weakened by chronic affections the difference in the pulse-rate in the two positions was much more marked; the absence of any slowing seemed to occur only in cases of marked inefficiency of the cardiac muscle.

This last method of studying the efficiency of the heart can be made use of anywhere and in patients in almost any condition of health, no instruments or assistants being required. Its frequent use with reports of findings may furnish valuable data as to its applicability and trustworthiness, and such use is therefore recommended. The functional capacity of the heart is, however, such a complex entity that critical study of several methods with comparison of the results should be attempted wherever external circumstances make this possible.

THE NERVOUS PRECURSORS OF TABES DORSALIS IN SECONDARY SYPHILIS.

IT is becoming increasingly evident, as diagnosis is perfected by more and more objective and therapeutic tests, that many of the precursory symptoms of tabes dorsalis depend upon the earlier manifestations of the lues from which it arises—certainly as some think, at least usually in the opinion of all. Now that the attention of syphilographers is being directed to this, cases are reported more frequently. Very significant in this regard is the coincidence with the peripheral-nerve disabilities of a lymphocytosis of the cerebrospinal fluid in all respects similar to that constantly noted in tabetics, and equally significant is the disappearance of this sign under intensive mercurial treatment, along with the symptoms which induced the patient to seek medical advice. Its frequent concomitant, the Argyll-Robertson pupil, was found in 1906 by

Buttino in many of 70 syphilitics examined with a view to determine this point.

Nageotte, as long ago as 1894, showed that the ataxia of tabetics arose from the implication of the posterior root fibers by a chronic indolent inflammation in the leptomeninges, produced by a toxin which he opined to be syphilitic. The actual nature of the toxin is, however, still *sub judice*; Fournier and many others call it parasyphilitic, and Ford-Robertson and Macrae strongly defend their hypothesis that it arises from paradiphtheroid organisms situated in the mucosæ and transmitting their toxins via the spinal nerves. The possibility of this has been shown by Orr and Rows as well as Homén.

As a contribution to the solution of this important problem, comes the case shown to the Paris Neurological Society on April 2 last by Ballet and Barbé (*Révue Neurologique*, April, 1908). It was that of a woman admitted for venereal roseola, in whom an abundant lymphocytosis disappeared only after 60 mercurial injections. A month and a half later, she suffered a relapse, with fever, headache, and meningeal symptoms, and lymphocytosis again. This time she died in spite of further treatment. Post mortem, no microscopic meningeal abnormalities were detected; but under the microscope the syphilitic involvement of the meninges was clearly evident. It resembled that of the case shown by Sezary about the same time to the Society of Biology of Paris. The spinal meninges presented subarachnoid infiltration and periarteritis, and abundant exudates of small round cells. The resemblance of this acute process to the more chronic meningeal changes always found in tabes (Nageotte, Spiller, and others) shows them to be essentially of the same nature. In neither case has the treponema been found, so we are as far as ever from knowing the part played by that organism in causing the lesions which the nervous system presents in syphilis.

The implication of the cranial nerves by this meningitis of secondary syphilis is similar to that of the spinal roots in tabes, and it is the cause of the facial neuralgias and palsies now being reported in that stage of the disease. They may occur, as in Jeanselme's case, even while the chancre is in evidence. The palsy is usually preceded by a sensation of cold: hence the superstition of facial paralysis *de frigore* still fixed in the popular mind. The real source of the "cold" on these occasions is the sensation of the patient, and this is due to the implication of the roots of other cranial nerves, such as the fifth, and that branch of the glossopharyngeal which Ramsey Hunt has shown to arise in the geniculate ganglion of tie facial, and to be distributed to a portion of the external auditory meatus and tympanum; hence, the cold in the ear supposition. Rigid inquiry and examination of the patient's sensibility after the method of Morriston-Davis will often permit a diagnosis of radicular as against a strictly peripheral source in facial palsy. This diagnosis will permit special treatment to be begun early and may enable us to secure a resolution of the morbid process before organization takes place, and before a permanent cranial-nerve palsy is established.

MYOPIA AND ITS PREVENTION.

One of the most important problems of school hygiene is the prevention of shortsightedness which is so apt to develop in children of the school age with the ever-increasing demands upon their eyes made by their advancement in the school curriculum. The difficulty of this task is increased by the fact that we possess no accurate knowledge of the causes of myopia nor of the conditions of the eye that predispose to this unfortunate affection. So far the work of fighting the development of myopia in school children and in the students of the higher institutions of learning has not been very encouraging. Thus Dr. Best, writing in the *Münchener medizinische Wochenschrift* for July 21, 1908, says that in 1866 the number of myopes among the students of the University of Breslau was 60 per cent.; in the year 1880 it was 59 per cent., and in 1902 it was 60 per cent. again, figures so uniform that any effect of preventive measures that have been taken during that time are certainly excluded.

An interesting fact is the progressive rise in the percentage of myopes in the higher institutions of learning; thus the highest class in a country school showed 2.6 per cent. myopia, the city school 9.8 per cent., while 55.9 per cent. of students ready to enter universities were nearsighted. That near-work is one of the most important causes of myopia cannot be questioned, for not only scholars and students become nearsighted but also any young adults habitually use their eyes for close examination of things at short distances, as for example, watchmakers, embroiderers, etc. But this certainly is not the only explanation for the wide prevalence of myopia among school children; otherwise not 60 per cent., but almost all would be affected, for the average amount of near-work done is about the same for all scholars. A contributory cause is found in an hereditary tendency to nearsightedness, the great majority of myopes giving the history of the affection in one or both parents. But the fact that myopia very rarely develops after the twenty-fifth year, even though much near-work may have to be done, shows that another factor is necessary in addition to near-work and heredity. Best thinks that this factor is intimately connected with the growth of the eye, its developing tissues being much more apt to be affected by the influences tending to produce myopia than the fully developed eye. The treatment of myopia is, of course, simple; it requires the use of glasses that correct the defect of refraction according to the needs and exigencies of each individual case.

It is the prevention of myopia that is more difficult and more important at the same time. The mere providing of plenty of light and air is not enough in this connection; the more directly harmful near-work ought to be limited in amount as much as possible, much of such work in our schools being altogether unnecessary and easily dispensed with. It is very questionable, for instance, whether the tedious exercises in "caligraphy" have much effect upon the formation of a good writing hand, though certainly such exercises have a most pernicious influence in bringing on nearsightedness. The suggestion of Best that the Gothtic type be com-

pletely abolished applies, of course, only to Germany, but many improvements in the printing of our school books have been suggested from time to time by oculists, and these ought certainly be considered more attentively by the School Boards than they have been in the past. Much of the kindergarten work is unquestionably injurious, and the beginning of myopia may often be traced to the strain put upon the eyes of the mites who should be romping out of doors instead of sticking pins in paper and otherwise straining their young eyes. The whole question of myopia is a very important one and is intimately connected with the general problem of school hygiene; the medical profession must insist that its authoritative opinion in such matters receives proper attention from the public bodies entrusted with the administration of schools. American statistics in reference to the development of myopia in the schools are much more favorable than those of Germany, but even here the greater number of cases of myopia are preventable by a properly arranged curriculum, especially in the lowest schools and the kindergartens.

TRYPSIN TREATMENT OF CANCER.

Little has been heard of late concerning the treatment of cancer by means of digestive ferments, although the matter has not been dropped but only shelved for a time. There are several medical men in the field both in Great Britain and in Germany who are pursuing researches in regard to various ferments in the endeavor to discover a cure for malignant disease, and perhaps the word shelved is too strong an expression to use in referring to the subject. Mr. Henry Morris, president of the Royal College of Surgeons of England, read at the recent International Surgical Congress at Brussels a paper on cancer, in which he dealt with the employment of trypsin in the treatment of malignant disease. He first ran over the long list of ferments which at the present time are being given a trial, namely, Amylopsin, in addition to trypsin (Beard), liver ferment (von Leyden and Bergell), placental tryptic ferment (Bumm, Leipmann), papayotin (Branch, Lucas); and, lastly, erepsin—which is contained chiefly in the intestinal mucous membrane (Cohnheim) but is common to all organs and tissues (Vernon)—has been recommended and is being experimented with by Shaw-Mackenzie.

Mr. Morris pointed out that only in regard to trypsin had sufficient time elapsed for any number of cases to be reported, and even with trypsin the time had been short for any definite conclusions to be drawn. Dr. J. A. Shaw-Mackenzie appears to have been the first to apply trypsin practically and has taken the position that the hope that trypsin would reach the site of the disease through the blood stream when injected at a distance "does not accord with the view generally admitted that the blood possesses certain antitryptic properties," and that 'the local atrophy and degeneration of a cancerous growth induced by subcutaneous injections of trypsin in the neighborhood of a tumor itself cannot be accepted as evidence of the successful treatment of cancer." Nevertheless, regarded from a scientific standpoint, it would seem that there is some reason to hope that a digestive ferment may be administered in such a manner as to exert a deterrent effect on the progress of malignant growths. On the other hand, it would be very unwise to assert that trypsin is a cure of cancer. Experiments up to the present may not have been altogether negative, but they have not been conclusive.

Negative Pathological Findings in Fatal Brain Disease.

Both neurologists and pathological anatomists are well acquainted with the fact that there may occur symptom-complexes furnishing clinical evidence of serious disease of the brain and yet the autopsy findings prove completely negative so far as the anatomical evidence is concerned. That this condition is not so rare as is generally thought is shown by the fact that Hochhaus is able to report seven such cases in the *Deutsche medizinische Wochenschrift* for September 24, 1908, all occurring in private practice within the course of four or five years. The symptoms for the most part simulated focal disease of the brain such as tumor and, indeed, Nonne used the term pseudotumor in describing several cases that were observed by him (*Deutsche Zeitschrift für Nervenheilkunde*, Bd. 27). Thus apathy, convulsions, difficulty in swallowing and talking, exaggeration of reflexes, paralyses of local distribution, and finally death in coma occurred in all the patients observed by Hochhaus. The uniformly negative findings at the autopsies lead Hochhaus to search for an explanation of the clinical picture in the disturbances of circulation limited to one focal center in some cases and of wider extent in others; other instances he considers to be examples of intoxication of some indeterminate nature not necessarily due to changes in the blood, but probably having its origin in local metabolic disturbances. On the other hand, remains of former lesions may also be responsible for the focal brain symptoms, for the mere presence of scars anywhere in the brain must be considered sufficient to produce any kind of symptoms referable to other localities, when the great interdependence of brain centers and nerve paths is remembered. Of course, there always remains the possibility of missing small anatomical changes in the brain, however careful is the performance of the autopsy; on the other hand, lesions not at present discoverable by the means of examination at our disposal may be, in the future, made plain by new diagnostic methods or better instruments of precision. The thing to be remembered at the present time is simply the rather frequent occurrence of such cases; this fact should lead one to great care in advising operation on the strength of focal brain symptoms only, so that the great success which brain surgery has enjoyed in recent years may not be marred by operations undertaken in the dark and ending in the failure to find any remediable conditions at the operation or any pathological lesions at the autopsy.

Pathogenesis of Eclampsia.

It is generally admitted nowadays that eclampsia is closely connected with some metabolic processes of pregnancy, the chief seat of which is to be found in the placenta. This view is well supported by the fact that immediate delivery of an eclamptic patient, with the consequent removal of the placenta,

is very frequently followed by a most surprising improvement in the condition of the patient who may then go on to perfect recovery; that the metabolism of the fetus is not always the cause of the disease is shown by the occurrence of eclamptic seizures in the presence of a dead fetus or even when the fetus has been expelled while the placenta still remains attached to the uterus. The ultimate factors of eclampsia, however, have not as yet been discovered. Schmorl claims that placental villi, breaking off from the mother organ and reaching the general circulation of the patient, become responsible for eclamptic seizures; Veit has shown that all placental tissue has some toxic effect upon animals; Liepmann claims to have proved that the placenta of an eclamptic patient contains certain specific toxins which prove fatal to animals if introduced into the peritoneal cavity. In the *Berliner klinische Wochenschrift* for October 5, 1908, Mohr and Freund report a different property of the placental tissue which may throw light upon the nature of eclampsia. Tallquist has lately succeeded in isolating a hemolytic substance from some tapeworms, which may be responsible for the grave anemia that often accompanies the infection with these parasites. Mohr and Freund have adopted his methods of treating placental extracts and have likewise succeeded in isolating a definite hemolytic substance in the form of a barium salt. Even very weak dilutions of this substance produced hemolysis of human blood corpuscles, while human blood serum was capable of preventing such hemolysis. The serum of the mother was especially effective, fetal serum showing very much less influence upon the destruction of the red cells. The authors consider it probable that the hemolytic substances of the placenta are in some way responsible for the phenomena of eclampsia; in what manner, however, these substances overcome the protective mechanism of the maternal blood and tissue fluids, that normally prevent such autointoxication in pregnant women, remains to be shown.

News of the Week.

The Second Harvey Society Lecture.—Dr. W. G. MacCallum, Associate Professor of Pathology in the Johns Hopkins Medical School, of Baltimore, will deliver the second lecture of the Harvey Society at the New York Academy of Medicine, 17 West 43d Street, on Saturday, November 7, at 8.30 P. M. Dr. MacCallum will speak on the subject of "Fever."

Army Medical Corps Examinations.—The Surgeon General of the Army announces that the first of the preliminary examinations for the appointment of first lieutenants in the Army Medical Corps for the year 1909 will be held on January 11, 1909, at points to be hereafter designated. The essential requirements are that the applicant shall be a citizen of the United States, between twenty-two and thirty years of age, a graduate of a medical school legally authorized to confer the degree of doctor of medicine, and of good moral character and habits, and shall have had at least one year's hospital training or its equivalent in practice. Full information concerning the examination can be procured upon application to the "Surgeon General, U. S. A., Washington." All applications must be completed and handed in on or before December 10, 1908. There are at present fifty-seven vacancies in the Medical Corps.

The Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about $180, will be made on July 14, 1909, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published. They must be typewritten, and must be received by the Secretary of the College on or before May 1, 1909. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college; other essays will be returned upon application within three months after the award. The Alvarenga Prize for 1908 has been awarded to Dr. William T. Shoemaker, of Philadelphia, for his essay entitled: "Retinitis Pigmentosa, with an Analysis of Seventeen cases Occurring in Deaf Mutes, Including Laboratory Examinations of the Blood and Urine in Eleven Cases."

Red Cross Christmas Stamps.—In order to raise money for the fight which it is carrying on against consumption, the National Red Cross has issued a stamp for use on Christmas letters and packages this year. The stamp was designed by Howard Pyle, and bears in addition to the name of the society, the inscription "Merry Christmas and Happy New Year." The stamps will be sold in sheets or in small books at the rate of nine for ten cents. They are, of course, not good for postage. This scheme for raising money was first tried in Denmark in 1904, under Government supervision, and has since been continued with great success. Last year the National Red Cross here took up the scheme, confining their work to the State of Delaware. Nearly $3,000 was cleared. This year the stamp will be distributed throughout the United States.

Accidents of the Rail.—According to the report of the Pennsylvania State Railroad Commission, 302 persons were killed and 3,514 were injured by accidents on steam and electric railways in the State during the months of July, August, and September. Of these 253 were killed and 2,039 injured on steam roads. Sixty-four per cent. of those killed on steam roads were trespassers, more than 25 per cent. employees, and less than 1 per cent. passengers. Of those injured on steam roads more than 72 per cent. were employees, more than 11 per cent. trespassers, and more than 10 per cent. passengers. Of those killed on electric lines more than 26 per cent. were passengers and only a little more than 4 per cent. employees, while of those injured more than 70 per cent. were passengers and less than 4 per cent. employees. At grade crossings 21 persons were killed and 48 injured by steam roads, while 1 was killed and 2 were injured by electric roads.

Plague in the Azores.—An outbreak of bubonic plague has been reported in Terceira, one of the Azores.

Milkmen and Butchers Fined.—Twenty-five milk dealers and an equal number of butchers were fined sums varying from $10 to $35 in the Court of Special Sessions, New York, on October 28. The milk dealers were charged with putting formaldehyde and water in the milk, and the butchers with preserving meats with sulphurous acid. Over one thousand dollars was collected from the fifty men.

Chicago and Clean Milk.—The Chicago Department of Health is taking a firm stand in the

effort to safeguard the city's milk supply, and will exercise a strict supervision over the farmers who ship the milk. On October 28 thousands of yellow tags were sent out to dairymen, on which they will be required to report twice a week all cases of contagious diseases appearing in their own families or the families of their dairy hands, or the absence of any such diseases. In the event of failure to make systematic and regular reports, the milk from the dairy will not be allowed to enter the city.

Cocaine Peddler Arrested.—Startling statements have been made recently regarding the use of cocaine among some of the boys in the high schools of Philadelphia, and one man was arrested on October 29, charged with peddling the drug. The prisoner was held in $2,000 bail, and because of the threats of the irate mothers of the victims, seemed glad to go to jail.

Medical School Inspection.—The medical inspectors of schools of Chicago examined 9,374 school children during the five school days of the week ended October 24, and excluded 424 on account of contagious diseases. The principal causes of exclusion were as follows: Scarlet fever, 6; contacts with scarlet fever, 12; contacts with diphtheria, 6; measles, 7; contacts with measles, 5; whooping-cough, 7; contacts with whooping-cough, 7; chicken-pox, 14; contacts with chicken-pox, 12; tonsillitis, 109.

Study of Russian Criminals.—It is reported that a laboratory for the study of criminals has recently been established in Russia under Government control, about $750,000 having been appropriated for the purpose. It is planned to work along the lines already mapped out by Arthur MacDonald of Washington, who has written extensively on criminal anthropology and has brought the subject to public attention many times.

Dr. Hamilton Wright of Washington sailed on October 27 from San Francisco to attend the International Opium Conference at Shanghai, which has for its purpose the assistance of China in the effort to abolish opium smoking among the Chinese people. Dr. Wright stated that among white people here opium smoking is confined almost entirely to the criminal classes, while among the Chinese of this country about 20 per cent. are confirmed opium smokers, 25 per cent. total abstainers, and the remainder occasional smokers.

Centenarian Celebrates.—Mrs. Mary Ann Souders, of Conestoga Centre, Pa., celebrated her one hundredth birthday on October 30. She is in good health and has unimpaired faculties; her life has been spent in Lancaster County, Pa.

D. Walter R. Gillette is seriously ill at the Roosevelt Hospital, New York, where he was operated upon for intestinal trouble recently.

"Santé," a journal of health, made its first appearance in September, 1908. It aims to present in popular language useful information concerning health topics, particularly information on the subject of tuberculosis. It is published at Asheville, N. C., under the editorial supervision of Dr. Paul Paquin.

Charitable Bequests.—The will of the late Mary J. Kelly of New York, which wac filed recently, provides for the gift of $500 to St. Francis' Hospital, and of a like sum to the Misericordia Hospital.

New Hospitals Opened.—The Elyria Memorial Hospital, at Elyria, Ohio, was opened for the reception of patients on Saturday, October 31. The building is a handsome one, four stories high, and thoroughly equipped.

The new Case Wing of St. Luke's Hospital, Cleveland, Ohio, was opened on October 18, when dedication exercises were held. The wing was built at a cost of $30,000 as a memorial to the late Dr. Guy Buttles Case.

Hospital in Seoul.—A magnificent hospital built by the Japanese Government was recently opened in Seoul, Korea. It is said to be one of the finest institutions in the East, and includes a school of medicine.

The Hospital Ship "Relief" has been detached from the Atlantic fleet now in the East, and assigned to the Pacific fleet. The vessel has been ordered to Callao to report. After leaving Manila the Atlantic fleet will divide into two squadrons, and the hospital ship will not be needed. She is under the command of Surgeon Charles F. Stokes.

Illinois Conference of Charities.—This conference put itself on record at its thirteenth annual session as favoring the establishment of a State Colony for Epileptics, a State Sanatorium for Tuberculosis, and the extension of the work of the visitation of children. A resolution was also introduced by Dr. W. E. Taylor, calling for a State law for physical and mental examination before the issuance of marriage licenses. The following officers were elected: *President,* Wm. C. Graves, secretary of the State Board of Charities, Springfield; *Vice-President,* Rev. James J. Shannon, Peoria; *Secretary,* Dr. Frank P. Norbury, Jacksonville; *Assistant-Secretary and Chairman of the Committee of Exhibits,* Harry N. Heiser, Peoria.

The Vermont State Medical Society held its 95th annual convention in Rutland, on October 23. Officers for the ensuing year were elected as follows: For the house of delegates, *President,* Dr. M. L. Chanler, Barre; *Vice-Presidents,* Dr. W. L. Slayton, Hyde Park, Dr. H. H. Lee, Wells River; *Secretary,* Dr. C. F. Dalton, Barre. For the society, *President,* Dr. C. W. Peck, Brandon; *Vice-President,* Dr. S. W. Hammond, Rutland; *Secretary,* Dr. C. H. Beecher, Burlington; *Treasurer,* Dr. B. H. Stone, Burlington; *Auditor,* Dr. J. H. Blodgett, Bellows Falls.

The Virginia State Medical Society at its thirty-ninth annual convention in Richmond. during October, elected the following officers: *President,* Dr. Stuart McGuire, Richmond; *Vice-Presidents,* Dr. O. C. Wright, Jarretts, Dr. E. T. Brady, Abingdon, Dr. Reid White, Lexington; *Secretary,* Dr. Landon B. Edwards, Richmond; *Treasurer,* Dr. R. M. Slaughter, Alexandria; *Chairman of the Executive Committee,* Dr. Louis Bosher, Richmond.

Chicago Gynecological Society.—At the October meeting, the following officers were elected: *President,* Dr. Henry F. Lewis; *Vice-Presidents,* Drs. Chas. E. Paddock and Rudolph W. Holmes; *Secretary,* Dr. Gustav Kolischer; *Treasurer,* Dr. Chas. B. Reed; *Editor,* Dr. Emil Ries; *Pathologist,* Dr. George Schmauch; *Councilor,* Dr. Robert T. Gillmore; and *Alternate,* Dr. Channing W. Barrett.

Scandinavian American Medical Society of Chicago.—At the October meeting of this society, Dr. O. Theodore Roberg was elected *President;* Dr. E. O. Olsen, *Vice-President,* and Dr. A. Klovstad, *Secretary-Treasurer.*

The Southern California Homeopathic Medical Society at its meeting in Los Angeles, recently, elected the following officers: *President,* Dr. Walter E. Nichols; *Vice-President,* Dr. W. J. Hawks; *Secretary and Treasurer,* Dr. F. S. Barnard.

Obituary Notes.—Dr. Henry Denton Nicoll, of New York, died of heart trouble on October 27, at New Windsor, N. Y., in the house where he was born sixty-four years ago. Dr. Nicoll was graduated from the College of Physicians and Surgeons of New York in 1866, and was a member of the American Medical Association, the Academy of Medicine, the New York State Medical Society, and the New York Pathological Society, consulting surgeon of the Woman's Hospital and the Nursery and Child's Hospital, consulting obstetrician to the Lincoln Hospital, and consulting gynecologist to the Presbyterian Hospital and the Home for Incurables. He was one of the organizers and administrators of the New York Infant Asylum, one of the founders and the treasurer of the Law and Order League of the State of New York, and a prominent member of the Presbyterian Church.

Dr. Harry Plympton, of Brooklyn, N. Y., died on October 29, at his home after a long illness, aged 50 years. Dr. Plympton was graduated from the Long Island College Hospital in 1880, and for two years was on the staff of the Kings County Insane Asylum, making a specialty of nervous diseases.

Dr. John E. Kohler, of New Holland, Pa., died on October 31, at the age of 57 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1873.

Dr. William S. McCall, of Fulton, Mo., died at his home on October 15, after a long illness, aged 74 years. Dr. McCall was born in Virginia, but his family soon after emigrated to Missouri, where he had since lived. He was graduated from the Missouri Medical College in 1857, and practised medicine for over forty years.

Dr. Henry A. Weymouth, of Andover, Mass., died at his home on October 22, after a few weeks' illness, aged 88 years. Dr. Weymouth was graduated from the Woodstock Medical College and also received a degree from Dartmouth. He had been in continuous and active practice in Andover since September, 1843.

Dr. Charles Franklin Rand, of Bellefonte, Pa., died at his home on October 13, from angina pectoris, aged 67 years. Dr. Rand, who was said to have been the first man to volunteer for service in the Union Army during the Civil War, and who ceived the first Medal of Honor presented by Congress, was graduated from the University of Georgetown, Washington, in 1873. During the war he spent three months in Libby Prison.

Dr. William R. M. Kellogg, city bacteriologist of Seattle, Wash, died on October 14, in the Seattle General Hospital, of chronic amebic dysentery, aged 33 years. He was graduated from the Johns Hopkins Medical School, Baltimore, in 1904, and had interested himself actively in the prevention of tuberculosis, publishing a small magazine called the *Coast Journal of Tuberculosis.*

Correspondence.

CEREBRAL RHEUMATISM.

To the Editor of the Medical Record:

Sir:—I am very grateful to you for bringing up the subject of cerebral rheumatism in your editorial of September 26, 1908, as it reminds me of some cases of the same disease I had occasion to observe, and especially of an interesting one I treated myself. You mention an article by Marcel Labbé in the *Tribune Médicale* for July 4, 1908, and another by R. Lépine in the *Lyon Médical* for July 12, 1908. Only the former was accessible to me. I must confess I cannot agree with the author in making the diagnosis of cerebral rheumatism in all three cases under discussion. According to my opinion, it would be more correct to designate them as cases of delirium tremens occurring during an attack of rheumatism, just as it is not accurate to speak of cerebral pneumonia in a case of pneumonia complicated by delirium tremens.

The author quotes, in support of his interpretation, the works of Trousseau, whose monograph on cerebral rheumatism is before me. Trousseau describes six forms of the malady, viz., the apoplectic, the maniacal, the meningitic, the hydrocephalic, the convulsive, and the choreic, but adds that this division is an artificial one. Of all these forms, it seems to me, only the last one stands in casual connection with rheumatism, while the other five are merely accidental manifestations of two diseases occurring simultaneously. This is confirmed by the relative frequency of the choreic form and by the efficacy of the salicylates in curing both chorea and rheumatism. Regarding the salicylates, my own experience tends to show that only large doses, say 2 drams salicylic acid or 2½ drams salicylate of sodium pro die for three or four days are productive of the best results in acute rheumatism.

But I feel I cannot accept Trousseau's conception of cerebral rheumatism. I should like to emphasize the fact in contradistinction to both Labbé and Trousseau that a form of cerebral symptoms occurs—or did occur in the presalicylic period—independent of alcoholism and psychosis, and that, strictly speaking, for these the term cerebral rheumatism should be reserved. In this view I am in harmony, among others, with Damsch, from whose discussion of inflammatory rheumatism in Ebstein and Schwalbach's "Handbuch der praktischen Medizin," 1905, Vol. III, page 824, the following is taken: "Exceedingly serious cerebral symptoms are observed in hard drinkers who react even at low temperatures with more or less violent delirium. The early appearance of the latter, its independence of hyperpyretic temperatures and the abatement of the symptoms, together with the diminution of the articular swellings, give rise to the thought that a toxic substance has directly influenced the brain, which may be considered as having been made particularly receptive by alcoholism. However, the severest cerebral symptoms, fortunately rare, also occur independent of alcoholism, and, being so conspicuous, lead to the designation of cerebral rheumatism. These symptoms are always accompanied by an excessive rise in temperature, unusual in rheumatism, to 41° C. (105.8° F.) and more. This form of the disease appears either at the onset or in the course of the malady, which starts in the usual way. Violent delirium, great motor restlessness, confusion, convulsions, etc., predominate. The pulse is rapid, small, and feeble; cardiac exhaustion soon manifests itself in facial cyanosis and death mostly occurs after a few days, accompanied by a further rise of temperature to 42°-43° C. (107.6°-109.4° F.). As the anatomical examination of the brain reveals no material changes, we are undoubtedly right in considering these cases to be due to an unusually severe form of infection."

Of the latter type were the five cases which occurred within two or three months in the winter of 1872-73 in the City Hospital in Leipsic, Germany. Four of these patients died in the way described above. The fifth was under my personal care. He was a little over 40 years old, single, a merchant by profession, not nervous, a moderate drinker and smoker, not strong, but rarely ill. He lived on a cold, damp main floor, and came to the hospital after a few weeks' illness His temperature was 102°-103° F., pulse corresponding, and all the joints of the lower and upper extremities were affected. The treatment at that time consisted in the administration of colchicum internally and fixing the joints by means of splints. He was sick in the hospital for two or three months when, shortly after the outbreak of the cerebral form in the four other cases, he developed the same symptoms. At the same time he suffered from about twenty bedsores, the largest, over the sacrum, as big as the palm of a small hand and exposing the bone. The fatal ending of the other four cases prompted me to apply a different treatment in this case, namely, hydrotherapy, which had proved highly successful in other fevers, but the use of which in acute rheumatism was considered nearly criminal.

When given the bath his temperature was 41° C. and the pulse was 144 and very feeble and irregular in strength. The water in the tub was about 80° F., and water of about 60° F. was poured over his head. After this had been done several times the delirium disappeared, and he exclaimed: "O, now I feel better." The bath was continued for ten minutes, after which his mind was entirely normal, his temperature fell in a few hours to 39°-38° C. (102.2°-100.4° F.) and his pulse to 110. After three or four days, during which the temperature

of the daily bath was gradually increased, his temperature and pulse became entirely normal, he regained his appetite and picked up slowly. The bedsores healed, the largest being closed by skin grafting, but as for the first weeks he could not make use of his limbs, massage was administered and passive and active movements undertaken, and after nearly one year from the beginning of his illness he was able to resume his vocation. I continued to see him frequently for eight years after his convalescence, during which he remained in good health and led a temperate life and was free from nervousness.

I ascribe the severity of his disease to the unhealthy conditions of his dwelling, and am inclined to believe that the germs of the disease—*Bacillus perfringens* does not seem to be universally acknowledged as its cause—are sometimes of a more pernicious nature than at other times, for it was striking that cerebral rheumatism occured in five cases within a few months, whereas we did not see any others for many years.

Oswald Joerg, M.D.

12 Schermerhorn Street, Brooklyn.

TREATMENT OF PNEUMONIA.

To the Editor of the Medical Record:

Sir:—I read with a good deal of interest Dr. Deek's paper on "Pneumonia on the Isthmus of Panama" as it appeared in the Medical Record of October 3. The paper was well written, and showed very careful attention to details, but I was disappointed when I read the appalling death rate that occurred—a death rate of from 25 to 58 per cent, the average 37 per cent. But when I read of the treatment—the quinine, the morphine, the strychnine, and the whiskey "ad libitum"—I saw a reason for the complications, and for the large death rate.

Let us see! In pneumonia there is one thing prominent above all others, blood poison, *blood loaded with toxins*, and as "the blood is the life," one must get rid of the toxins, or one will soon have a dead patient. I take the record of the treatment as Dr. Deeks gives it. Quinine is the first remedy; but does that help to throw off the toxins? No, it increases them. The condition of the blood is made worse by the use of quinine. It is the same with morphine and whiskey, both adding to the toxins of the blood and hastening the end. Whiskey does more than poison the blood; it stimulates the heart to increased labor and hastens the condition so dreaded—heart failure. There is not a single thing in the treatment as given in this article that tends to relieve the blood of its toxins, but everything given increases the blood poison.

If it is true that the one thing prominent in pneumonia is blood poison, then it is absolutely necessary to get rid of the poison, and if one can get rid of this one will save his patient, and the quicker the poison is got rid of, the better for the patient.
